Metallurgical & Chemical Engineering

Being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine

Published Monthly to August, 1915,
Semi-monthly Since September 1, 1915.

Volume XIII

From January to December, 1915

436838
3. 7. 45

NEW YORK:
McGRAW PUBLISHING COMPANY, Inc.

INDEX TO VOLUME XIII

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).

A

ABBE Engineering Co. ... 691
Abbe, Paul O. ... 745, 918
Abrasive Material Co. ... 860
Abrasives, for grinding steel. Kalmus. (P.) ... 762
Accident prevention in the chemical industries. Keough ... 731
Acetone from hardwood distillations ... 30
ACID:
——At close of 1915 ... 710
——Hydrochloric. Electrolysis ... 964
——Nitric. Electrolysis ... 964
——Orthophosphoric ... 964
——Sulphuric. Concentration. Mason ... 17
—— Concentration in silica dishes. Marshall ... 136
—— Contact process. Brockbank. (P.) ... 971
—— Electrolysis ... 964
—— Erecting plants ... 846
—— New agricultural use for ... 648
Acid process for electric steel. Müller. (S.) ... 640
Acid-resisting alloy. Parr ... 712
Acid treatment of gold precipitate. (S.) 118
Actinometer. Kershaw ... 970
Addicks, Lawrence (Photo) ... 315, 708
Advice to consulting metallurgists. Blythe 442
Aeration treatment of sewage. Bartow ... 901
AGITATOR:
——Dorr in series ... 13
——Dorr ... 91
——Dorr. (P.) ... 392
——For slime pulps. Vandercook (P.) ... 924
——Trent, At West End mill. Carpenter. 671
Agriculture, New use for sulphuric acid 648
Ainsworth & Sons, Wm. G. ... 745
Air compressor, Continuous running. Nash ... 460
Air-gun for repairing furnaces ... 416, 529, 582
Air-lift pumping. Sullivan Machinery Co. ... 392
——Berggreen (S.) ... 507
Alarm, Bottle-filling. Hall ... 347
Alaska Gastineau Mill ... 273
Alaska Gold Mines Co. ... 16
Alaskan Railroad of the Government ... 271
Albumin, Coagulation by electrolytes. Bancroft ... 317
Alcohol, Rewards for methods of utilizing ... 352
Alcohol from hardwood distillation. French and Withrow ... 30
Alkalies, Electric furnace manufacture of. Acker (P.) ... 764
Alkalies, Situation at close of 1915 ... 710
Allis-Chalmers Co ... 860
Allotropy of metals. Vosmaer ... 535
ALLOYS:
——Acid-resisting. Parr ... 721, 973
——Alloy steels. Norris ... 739
——Aluminium. McAdams (P.) ... 504, 570
——Aluminium, Bronze. Corse ... 712
——Copper, Titanium, Magnesium. Vickers (P.) ... 701
——Iron alloy for dynamo-electric purposes. Rühel (P.) ... 249
——Iron, Cobalt, Chromium. Hayes (P.) 701
——Nickel, Copper, Lead ... 644
——Patents relating to electroplating, 196, 268
——Platinum and Osmium. Zimmerman (P.) ... 762
——Pyrophoric alloy suit ... 145
——Rapid analysis of bearing metals and high-copper content alloy. Lutts 347, 370
——Silver and cadmium ... 378
——Ulcoloy, A new copper-lead alloy ... 378
——Zirconium, Iron for lamp filaments Brown (P.) ... 924

ALLOYS: (Continued.)
All-sliming cyanide plants in California. Palmer ... 617
Alum for water purification. Hoover (S.) 508
Alumina in steel. Comstock ... 891
——Fitz Gerald ... 936
ALUMINIUM:
——Alloy. McAdams (P.) ... 504
——Alloy (P.) ... 570
——Autogenous welding. Pannell ... 712
——Bronze alloys. Corse ... 712
——Chloride process for refining high boiling petroleum oils. McAfee. 592
——Coating on different metals (colorizing). Ruder ... 325
——Consumption in 1914 ... 546
——Die casting. Pack ... 712
——Effect of enhanced value on silver ... 526
——Furnace for producing alumina. Schwan (P.) ... 569
——Melting aluminium chips. Gillett ... 712
——Nitride manufacture. Bunet (P.) ... 504
——Nitride-Askenasy ... 966
——Plating, Patents relating to (D.) ... 341
——Plating On. Hall (P.) ... 570
——Price changes ... 706
——Southern Aluminium Co.'s plant ... 832
——Statistics ... 710
——Treatment of surfaces for plating. Roux (P.) ... 570
Alumino, Vanadium. Clark ... 712
Alunite deposits being developed in Utah. (See also Potash), 482, 526, 582
Amalgamation. Relative Efficiency of various amalgams. Thomson, Keffer ... 367
Amalgamation tailings. Determination of mercury ... 896
Amalgamation tests. Sharwood (S.) ... 927
Amendment of the Patent Laws ... 76
America. Electrochemistry in ... 1
American Bitumastic Enamels Co ... 691
American Blower Co. ... 717, 918
American Chemical Society, 210, 351, 419, 494, 782
——New York Section ... 244
——New Orleans Meeting ... 280
——Southern California Section ... 530
——Seattle Meeting ... 587
——National Exposition ... 691
——New York Section ... 710
——University and Industry ... 885, 941
American Cyananid Co. ... 213
American Electrochemical Society in its external relations. (Pres. address.) Lidbury ... 277
American Electrochemical Society, 185, 210, 351, 419, 494, 782
——New York Section ... 211, 241, 884
——Niagara Falls Section ... 651, 776
——Atlantic City Meeting ... 314
——San Francisco Meeting ... 654
——Exposition of Chemical Industries, 691, 697, 700
American Electroplaters' Society ... 176
American Foundrymen's Association Convention, Atlantic City ... 712
American Hard Rubber Co. ... 691
American Institute of Chemical Engineers, 351, 418, 710
——Philadelphia meeting ... 41
——Los Angeles meeting ... 530
——San Francisco meeting ... 603
——Exposition of chemical industries, 691, 699
American Institute of Metals, Atlantic City meeting ... 712
American Institute of Mining Engineers, 98, 177, 208, 419, 887
——Montana Section ... 196
——San Francisco Meeting ... 654
——Columbia Section ... 904

American Iron and Steel Institute:
——Corrosion problem ... 420
——Cleveland meeting ... 830
American Mining Congress:
——Resolutions ... 42
——San Francisco ... 652
American Ore Flotation Co. ... 348
American Paper and Pulp Association, 520, 691, 700
American Potash Co. ... 860
American Shop Equipment Co. ... 586
American Smelting & Refining Co. ... 274
American Transformer Co. ... 691
American Vulcanized Fibre Co. ... 746
American Window Glass Co. ... 800
American Zinc, Lead and Smelting Co. ... 275
Ammonia, Lymn ammonia and producer-gas plant ... 456
Ammonium sulphate production in 1914 (S.) ... 638
Amorphous solids. Chemistry. Lewis ... 921
Ampco bronze ... 931
Ampere-hour meter for electrolytic works ... 191
Anaconda Copper Co. ... 207, 403, 526, 557
Anaconda, Powdered coal plant ... 333
Anaconda Copper Co., Powdered coal practice. Mathewson ... 728
ANALYSIS:
——Analoid method for phosphorus determination. (S.) ... 191
——Bearing metals and high copper content alloys. Lutts ... 346
——Brazilian monazite sand ... 403
——Carbon determination with platinum boats. Siever ... 525
——Carbon determination by the combustion method. Rich ... 347
——Carbon combustion apparatus. Cox (P.) ... 504
——Carbon and oxygen in steel and tungsten powder. Electric furnace. Johnson ... 17
——Chromium and vanadium in steel. Rich and Whittam ... 238
——Electro-analysis. Smith ... 327
——Determination of antimony, arsenic, bismuth, cadmium, copper, lead, silver, tin, by electrolysis. Schoch (S.) ... 568
——Estimation of aromatic hydro-carbons in cracked petroleum. Rittman, Twomey, Egloff ... 682
——Gold and silver in cyanide solutions. Bahney (S.) ... 252
——Gold-bearing cyanide solution (S.) ... 447
——Manganese in ferrovanadium. Clark ... 155
——Mercury in amalgamation tailings ... 896
——Nickel. Calhane ... 8
——Quantitative blowpipe Richards ... 137
——Spectroscopic steel ... 463
——Standardization of acid solutions. Randall and Scalione ... 787
——Sulphur dioxide method for hydro-carbon analysis. Rittman and Moore ... 713
Anderson, H. G. S. ... 402
ANILINE DYES:
——British industry ... 124
——Situation. Stone ... 663
——Situation before N. Y. Section Society of Chemical Industry ... 779
——Statistics. Stone ... 710, 828
Anodes, Manganese peroxide. Isherwood (P.) ... 641
Anodes for plating, Patents relating to. (D.) ... 403, 463, 575
Anti-dumping clause ... 705
ANTIMONY:
——Allotropy of. Vosmaer ... 536
——Electrolytic refining. Betts ... 848
——In Mexico ... 633

ANTIMONY: (Continued.)
——Mining in Japan 890
——Price changes 706
——Smelter 402
——Smelter on Pacific Coast 501
——Shipments from Central China 586
Applied Chemistry. Baekeland 677
Arc. Flaming. Carbons. Chemistry. Moore. 52
Arc. In vapors and gases at reduced pressures. Darrah 915
Archibald, W. M 978
Arcs. Unstable states in arc and glow. Cady 866
Argall, Philip 340
Argo Mill, Colorado 421
Arizona Copper Co 40, 207, 290, 535
Arizona smelters. Equipment 904
Aromatic compounds. Electrolysis of. Forbes 212
Armco iron 710
Armstrong, Theodore. (Photo) 130
Armstrong Cork & Insulation Co 792
Army and navy officers go to private plants 519
Aromatic hydrocarbons. Sulphur dioxide. Method of Determination. Rittman and Moore 713
Arsenic trioxide. Vapor pressure of 633
Asbes. Plant and wood for making potash. Bradley 841
Asphalt. Mining and preparing Trinidad. Pierce 697
Assaying. Cupellation losses. Sharwood. (S.) 927
Assaying. Wood-burning furnace. Edmands. (S.) 924
Assay Balance. Mechanical transference of weights 512
Association of Iron and Steel Electrical Engineers 392
Aston, James 340
ATMOSPHERIC NITROGEN FIXATION:
——Clennell 756
——Du Pont (P.) 642
——Landis (P.) 213
——Peacock (P.) 251, 642
——Russia 828
Atmospheric pollution of towns. Kershaw 967
Ault & Wiborg 691
Aurora Mill 16
Austria-Hungary. Chemical industries and the war. Donath and Ulrich. (S.) 639
Automatic Weighing Machine Co 691

B

BADGLEY, C. W 575
Baekeland, L. H. (Photo) 708
Bag house for lead smelter. (P.) 122
Bakelite. Suit decision 411, 592
Baker & Co., Inc 64
Baker-Hansen Co 745
Baker Mines Co 947
Baker, J. T., Chemical Co 691, 745
Baker, Charles W 820, 878
Baker, Robt. E 196
Balances. Analytical and laboratory. Christian Becker 631
Banks, John H 267
Barber Asphalt Company. Trinidad asphalt 697
Bardwell, Carlos 402
Bardwell, E. S 462, 520
Barium. Industry in U. S. Toch 710
Barytes 710
Base-metal situation 416
Battery. Two-fluid primary. Regeneration. Hess. (D.) 66
Bausch & Lomb Optical Co 644, 745, 802
Bauxite Production in 1914 546
Beach-Russ Co 691
Beauchamp, F. A 878
Beaver Consolidated Mines, L't'd 473
Becker, Inc., Christian 691
Beckers, W., Aniline and Chemical Works 691
Belmont Milling Co. Tonopah. Jones. (S.) 811
Bender, L. V 131
Bennett, F. A 267
Benson, H. K 646
Benzol plants 481
Benzol Products Co 691
Benzol from California oils 828
Benzol. Statistics 710
Berolzheimer, D. D 340
Beta Iron. Sauveur. (Poem) 352
Bethlehem Foundry & Machine Co 691
Bihn-Jones device for raising liquids 876
Bilharz, O. M 267
Birkinbine, J. L. W 820
Bismuth. Allotropy of. Vosmaer 535
Bit of economic mineralogy 581
Black Oak Mill. Palmer 622
Blake, Lucien I 196, 340
BLAST FURNACE:
——Blast efficiency and regulation. Burman 624
——Carbon bricks. Harden 202
——Charcoal. Wet ores in. Lee 882
——Chemical principles. Johnson ...536, 634
——Copper in Canada 16
——Filling of. Johnson 161, 227
——Handling iron and cinder Johnson. 43, 85
——Plant auxiliaries and general arrangement. Johnson ...373, 429, 495
——Thermal principles. Johnson 718 787, 833, 905
Blowpipe analysis. Quantative. Richards 137
Blue vitriol from Nichols Copper Co 484
Boiler feed water purification. Brown .. 156
Boiler feed pump 978
Boiler plugs. Tin. Investigation. Burgess. 712
Bolivia. Exports 15
Bomb calorimeter determinations. Effect of high ignition. Voltages. Dittus 480

Butte & Superior Copper Company ...13, 207
Butte. Labor conditions 16
Buying and selling of ores and metallurgical products. Fulton (S.). 640
By-product coking 649
Byron Jackson Iron Works 745

C

CALCIUM carbide. Manufacture from carbide fines. Hartenstein (P.). 763
Cadmium. Allotropy. Vosmaer 953
Calcium carbide. New process. Becket. (P.) 642
Calibration. Curve for horizontal cylindrical tanks 511
California and the International Engineering Congress 579
California. Gold and petroleum yield in 1914 847
California. Mineral production in 1914 827
California Slime Extraction Co 617
Callow pneumatic process of flotation 571
Calorimeter determinations. Effect of high ignition. Voltages. Dittus 480
Caloris Company 279
Calorizing metals. Ruder 325
Calumet and Arizona Mining Co 473
Cameron, F. K 978
Cam for stamp mills. (S.) 118
Canada mineral production 662
Canada. Salt industry 846
Canadian Mining Institute 184
Capsule apparatus for sulphuric acid concentration. Mason 17
Carbolic acid 710
Carbolic acid. Extraction from oils of coal tar distillation. Mason 293
Carbolic Acid. Synthetic. Ney 686
Carbon. Determination by the combustion method. Jennings 70
Carbon. Electric furnace preparation. Hennebutte. (P.) 817
Carbon anodes in copper sulphate electrolysis. Addicks 748
Carbon bisulphide. Removal from Coal-gas 239
Carbon bricks for blast furnaces. Härden 202
Carbon dioxide tube lamp. Moore 885
Carbonitride manufacture. Peacock (P.). 642
Carbons, Chemistry of flaming arc. Moore 52
Carbon tetrachloride 710
Carborundum exhibit at Panama-Pac. Expos. 458
Cariman Mining and Milling Co 477
Carnotite ore treatment. Danforth, Samuels and Martersteck. (P.) 187
Carnotite ores. Concentration of 273
Carnotite. Extraction of radium, vanadium and uranium 965
Carstens, C. E 267
Case, Flotation testing machine 930
Casting iron. Johnson 43
Cast iron, Natural chill and its significance in the manufacture of malleable castings. Thrasher 39

Electrochemistry in America

"There is a divinity that shapes our ends, rough hew them how we will." This quotation from Shakespeare which E. G. Acheson has placed at the head of the story of his life, might well be used as the leitmotif of a history of chemistry in America by any one who has the courage to write it. But who would in these days when history is in the making and American chemistry is expected, as never before, to solve problems and do things? Yet just because a detailed review of the many things that have happened during the past year in the different branches of the American chemical industries is inopportune now, the moment seems to call for a rough perspective sketch of at least a few tendencies which have been active in the shaping of American chemistry. If inspiration such as past achievements can give, is needed now by American chemists, it could not be found anywhere more markedly than in the story of American electrochemistry. No other branch of industrial chemistry has so distinctly the smack of American soil, shows so clearly the individuality of American conception and execution, as electrochemistry.

The story of American electrochemistry comprises not much more than the last two decades. Yet like anybody who is anything, American electrochemistry has a past. Without making impossible claims of impossible ancestors, we will mention one single name—Robert Hare of Philadelphia. He is perhaps most widely known as the inventor of the oxyhydrogen blowpipe, about which he presented a paper in 1801 before the Chemical Society of Philadelphia (by the way, the first chemical society in the world). But his influence was even broader in that he was the earliest American scientific experimenter and discoverer in electrochemistry. Hare interested himself in improvements in primary batteries. He introduced his "deflagrator" concerning which we quote from Silliman (from the delightful chapter on Hare in Edgar F. Smith's "Chemistry in America"): "Although the discovery of the constant battery by Daniell and of the double combinations of platinum or carbon with amalgamated zinc and nitric acid have rendered the old forms of this instrument no longer as useful as formerly, it is not less a proof of the merit of Hare's apparatus that Faraday, in 1835, after having exhausted his ingenuity and experience in perfecting the voltaic battery, found that Hare had already, nearly 25 years before, accomplished all that he had attempted, and with a noble frankness, worthy of all praise, he at once adopted Hare's instrument as embodying the best results then possible."

But even more remarkable is what Robert Hare was able to accomplish with his primary batteries as only

source of current. He improved Davy's electrolytic apparatus and process for obtaining the amalgams of calcium, barium and strontium from their chlorides. And he built an electric furnace which was the first electric furnace ever constructed and employed. Dr. C. A. Doremus presented an interesting paper on this furnace a few years ago before the American Electrochemical Society and the claim has been made that Hare must have produced in his electric furnace calcium carbide, phosphorus, graphite and metallic calcium. Whether he did or not, really matters little. But if he did, the question suggests itself: why did it take some 70 or 80 years to rediscover those substances and make them industrially?

One reason would be rather obvious. It is almost getting tedious to repeat that electric power cost is usually a large item in the cost sheet of electrochemical processes. With primary batteries as the only source of current, any development of industrial electrochemists and of electrical engineering in general was a clear impossibility. But when the dynamo made its commercial appearance it was quite natural that electric lighting and the mechanical applications of electricity such as traction and power transmission and distribution, first attracted the inventive talents of electrical engineers. Only after they had succeeded it became possible for the electrochemist to step in.

The work of the electrochemist is directed toward two aims. One is the production of electrical form chemical energy, the other is the reverse problem, the production of chemicals and chemical effects by electrical means and the storage of energy in chemicals. In the former field nothing that has the faintest resemblance to a revolutionary advance has been made in the design of the primary battery, which is still essentially based on the use of zinc as "fuel." The carbon battery is still a mere dream. Storage battery engineering, on the other hand, has passed with success through an extremely active career. In the development of the lead storage battery Brush in this country, like Faure abroad, devised in the early eighties of the last century an important improvement in the Plante lead cell consisting in the application of active material to a conducting support. Many smaller improvements in the lead cell have since been made by uncounted American battery engineers. But the only radical departure has been due to Thomas A. Edison, who invented and developed the iron-nickel alkaline storage battery.

Nor is this by any means Edison's only contribution to electrochemistry. Edison's revolutionary pioneer work on the carbon filament for the incandescent lamp was intrinsically of a chemical nature. All our modern illumination methods are essentially based on chemical research. And the indirect influence which Edison's personality has had on the evolution of American electrochemistry in shaping the career of such men as Acheson cannot be overestimated.

For this reason a few words may be said on Mr. Edison's well known method of working or procedure in invention, because in a way it is characteristic of the methods of working of the few big early electrochemical inventors who became the founders of the modern electrochemical industries of this country. Edison's principle is to take nothing for granted, to try everything, every material and every method—whether apparently possible or impossible, practical or impractical, probable or improbable—and to observe with utmost care in any case what happens. "Inspiration is only another way of spelling perspiration" is one of his slogans.

After all, this method of working is the only method possible in a new field in which there are absolutely no analogies to go by. This method was the only one possible in the pioneer work which led to the foundation of the big industries of carborundum and alundum, artificial graphite, calcium carbide, and so on, in the electric furnace.

When the electric furnace had been invented it was a tool to be used and abused. A very distinguished electrochemical inventor once said that it was all foolishness to rely on theoretical principles in high-temperature electric-furnace work, as there were neither analogies nor quantitative figures available. All that could really be done was to try an experiment and see what comes of it and observe whether the product is good for anything. This may sound a little rough, but it states the case truthfully with utmost frankness and it emphasizes in a very modest way the requirements in the mental make-up of an experimenter who proceeds along such lines. He must have the faith of a child, the courage of the pioneer who blazes the trail, and a power of keenest observation of the smallest indications of usefulness which appear in his experiments and which then become his guide for further work. Each of these mental requirements is rare, their combination is given to very few.

Acheson's glorious life work is a fine illustration of the momentous scope of various industries which, in the hands of a strong individuality, may grow with almost logical necessity out of a single and apparently exceedingly simple chemical reaction—in Acheson's case the reaction beteween silica and carbon. Acheson carefully noted anything he found in his carborundum furnace. And when he found something that was what it should not be, it was not despised as an undesirable impurity (which it would have been to an ordinary manufacturer), but it became to Acheson an indication of what would happen under changed physical conditions and a guide to new work. Thus the carborundum industry was followed by the industries of artificial graphite, silicon and siloxicon.

It is evident that work of this kind which creates new industries can only be carried through to success by strong individualities which naturally become a source of inspiration to others so that their work becomes a nucleus around which the work of others on a broader field crystallizes. Thus we have the early pioneer work of the two Cowles brothers which led to experimental work in many fields and to the industrial manufacture of aluminium alloys and other alloys in the electric furnace. And as a further perhaps purely psychological result, Cleveland became for a time an active center of electrochemical endeavor. Thomas L.

Willson, of calcium carbide fame, was once in the employ of the Brush Company in Cleveland, and Edward R. Taylor, the inventor of the carbon bisulphide electric furnace, also belongs to the group of old independent Cleveland electric-furnace men. Herbert H. Dow worked out at the Case School his process for sodium chloride electrolysis, and David H. Browne successfully separated nickel and copper from Sudbury ores for a series of years by an electrolytic process at Cleveland. And Cleveland is still the home of the amorphous carbon electrode industry, although the largest electrodes for electric furnace work are now made at Niagara Falls.

In fact, the chief center of electric-furnace activity in this country and in the world is now Niagara Falls. There we have the big electric-furnace industries of artificial abrasives, of calcium carbide and calcium cyanamide, of phosphorus, of silicon, and so on; of electrolytic-furnace processes we have the Hall aluminium process and the Castner sodium process, of electrolytic processes the manufacture of caustic and chlorine on a very large scale, of chlorate, etc., almost all processes used there being products of American genius. There are very few imported processes in use at Niagara. And it is but the plain truth to say that the Niagara Falls electrochemical plants demonstrate in broadness of scope and detail of execution in the highest degree the application of the American type of industrial genius to chemical industry.

While we are writing these lines, the news reaches us of the death of Charles M. Hall on December 27 at Daytona, Fla., where he had gone a few months ago in the hope of final recovery from a sickness of several years. Thus Hall has followed shortly Heroult, his friend and competitor in aluminium fame, into eternity. Hall in this country and Heroult in France invented simultaneously and independently the process by which aluminium is now made. And to Hall belongs the credit for having started the electrochemical settlement at Niagara. When in 1893 the Niagara Falls Power Company completed its power house the next step of finding customers for the power was not so easily solved, until the Pittsburgh Reduction Company with the Hall aluminium process broke the ice. How one after the other electrochemical industries followed is history.

It is impossible to go any more into details. Only with respect to the electrolytic production of caustic and bleach—a very flourishing industry just now since on account of the European war the importation of European bleach has stopped—we may point out the abundance of processes in successful commercial use. For the diaphragm process Le Sueur and Dow were early pioneers in this country, while probably the latest cell of this type is the German Billiter-Siemens & Halske cell, in use by the Niagara Alkali Company. The Pennsylvania Salt Company uses the Gibbs cell at Wyandotte. The mercury cathode process is represented by the Castner-Kellner cell in use on a large scale by the Castner Electrolytic Alkali Company at Niagara Falls. Analogous in principle to the mercury cathode cell, but using a fused electrolyte and a fused lead cathode for alloying with the sodium, was the ill-fated Acker process at Niagara. The Townsend cell is of decided originality; while it is usually classed as a diaphragm cell, it is really much nearer the mercury cathode cell, since the caustic soda as soon as formed is carried away by kerosene; in its development on a large scale for the Hooker Electrochemical Company at Niagara, Dr. Baekeland, among others has distinguished himself.

In the problem of the fixation of atmospheric nitrogen the credit of having done the pioneer work belongs to Bradley and Lovejoy, though their plant at Niagara was finally a failure. While the technical efficiency of output per kilowatt-hour in their process was practically the same as it is in the successful Birkeland-Eyde process in Norway, the question of commercial success turns on the cost of power and the power cost at Niagara is four or five times that in Norway.

But another application of electrochemistry to gas reactions, also of American origin, is proving a big industrial success in this country. The Cottrell process of precipitating dust and generally any liquid and solid particles from fumes and gases, now finds a steadily widening field of usefulness in smelters, refineries, chemical works, gas, cement and general industrial plants.

We have not even touched yet on the immense field of the applications of electrochemistry to metallurgy. But this is "another story" that may be left for another occasion. Surely even in the limited field we have considered, American electrochemists have shown that they stand on their own feet and can create industrial empires. When this country needs the help of the chemist —and this will be more and more the case—American chemists stand ready to do their duty.

Progress in Gold and Silver Metallurgy in 1914

As one of the most suggestive developments of the year we note the remodeling of the Dome mill, in the Porcupine district of Ontario. With the increase in reserves and the coincident decrease in grade of the ores of this mine, the milling capacity was largely increased and the flow-sheet rearranged to accommodate the lower grade ore to be treated. These conditions were met, as, in our opinion, they must always be met, by discarding all-sliming and supplementing the slime treatment with the installation of sand vats, a portion of the concentrates being reground in tube-mills.

Fine grinding, as with tube-mills, has done much for the advancement of the metallurgy of gold and silver, as indeed it is now doing for almost all concentration projects, of whatever metal-bearing ores. It has fairly won its place as standard practice and must continue to be a part of every scheme of treatment. But we have sometimes thought that our American metallurgists have been overzealous in their quest of the maximum extraction, and that fine grinding may at times have been unwisely developed to the extreme of total sliming. Tube-milling, particularly when carried to the point where all-slime treatment may follow it, is an expensive operation, and as the grade of the ore decreases, the in-

creased recovery due to the reduction in size of the particles may very well fail to offset the cost of power, material, and attendance expended for the reduction.

We think it may fairly be said that the lower the grade of the ore, the greater difference will exist between the maximum percentage of extraction obtainable and the maximum economic extraction, and that the latter will be lower as the grade of the ore is lower.

Briefly, we consider the work at the Dome to be soundly conservative; and from it we turn to examine, with interest, the radicalism of Mr. Jackling, as exemplified in the proposed Alaska Gold Mines mill.

Perhaps no work of recent years will be watched as closely by metallurgists as will this application of the accepted practice of the porphyry coper mills to the requirements of gold metallurgy. Breaking is to be followed by rolls, roughing tables, classifiers, regrinding plant, and concentrators, the aim being for concentrating efficiency rather than high recovery by amalgamation. Revolutionary as it seems, it may be inspired, and certainly not only the prestige of its sponsor but many strong features of the process itself merit the attention it will receive. To the onlooker this undertaking is particularly timely, since the increase in the falling weight of stamps has ceased, both abroad and in this country, where we understand that tests by one of the largest producers have indicated 1250 lb. as maximum falling weight obtainable without loss of efficiency.

With the continued development and widening application of cyanidation, amalgamation has in many instances been abandoned; in many others reduced to a position of minor importance. It is said that a good mine is a long time in aying; the same may be said of a good process, and we feel that amalgamation, far from being moribund, has its distinct field, doubtless narrower than formerly and yet of sufficient consequence to justify its consideration as a live process.

We note, in fine grinding, a drift toward shorter tube-mills, which has doubtless been influenced by the well-merited success of the Hardinge conical mill.

In the treatment of slime, undoubtedly the most interesting development of the year is the steady increase in the number of plants using continuous counter-current decantation for washing and dewatering slime This process, which at the time of its first application by John Randall failed through the unsuitability of the mechanical devices then available, has now, with the development of dependable slime-thickening tanks, fairly won a place beside the filtration processes, and is said to be doing most effective work. We look for its further development during the coming year

In precipitation, zinc, whether in the form of dust or shavings, but with the former making constant gains, continues to be generally used. The aluminium dust process, as used at the Nipissing low-grade mill, has brought forward the first innovation in this branch of the science which has come to the point of continuous and successful operation.

Conditions may no doubt exist where this precipitant, even though more expensive, has strong claims to superiority, but in our judgment they will be comparatively few and in all likelihood will be confined to ores where silver is the dominant metal, as the comparatively high alkalinity which is essential to the method would in certain instances inhibit extraction from gold-bearing sulphides. Broadly speaking, the process follows the general scheme used in precipitating with zinc dust, which has become the standard American method, except in small installations.

Passing from the metallurgy of gold, we consider the progress in the treatment of silver-bearing ores, in so far as the two metals may be considered separately.

Here we find the most interesting work of the year in the methods of the Nipissing mills, where the aluminium precipitation method, already discussed, is accompanied by the very interesting desulphurization method of Denny, wherein the ore, in a solution of sodium hydrate, is agitated in the presence of aluminium plates. As if this were not enough, the amalgamation method of their high-grade mill (although this perhaps antedates the period under review) is a further contribution from this source. All these innovations illustrate the constant widening of the field of cyaniding and the possibilities still awaiting the careful investigator.

In this connection we feel that the paper by Mr. G. H. Clevenger, in the July *Bulletin* of the American Institute of Mining Engineers, merits most careful reading by all metallurgists, as an illuminating and thoughtful article, delightfully sane in its consideration of the questions which it discusses, and, indeed, well worthy of the best traditions of the Institute.

In the course of this discussion, Mr. Clevenger expresses his satisfaction that, in the desulphurization process to which we have already referred, some one has at last brought forward a process depending upon reduction, as a foil to the innumerable oxidation methods now extant. We might continue the thought and express to the able staff of the Nipissing our appreciation of their efforts to give us some really valuable contributions to the development of the chemical side of cyanidation, which, coming as they do after years when all development seemed to be along mechanical lines, are more than welcome.

Chloridizing-leaching, as practised at Park City, and described by Mr. Theodore P. Holt, is another interesting contribution to the year's technology. The chloridizing roast is given in the Holt-Dern roaster, at a cost of less than $0.17 per ton, and the total cost of milling is placed at not over $1 per ton, with extractions of gold, silver and copper above 90 per cent.

In the technical press, two interesting controversies have continued their perennial course. The estimation of tonnage by specific gravity methods has grown in popularity, owing to its simplicity and cheapness. The experience of the Nipissing mill, cited by Mr. Johnston, confirms this view. He shows that the determination of weight, taken by a registering scale on the ore as it entered the mill, was checked over a period of seven months against the usual method of specific gravity tonnage determination, during which time a variation of only one-eighth of 1 per cent was noted. From this it seems reasonable to conclude that an intelligent application of the specific gravity methods can be depended upon for accuracy.

Not so satisfactory has been the discussion of the work of crushing, wherein the advocates of the laws of Rittinger and of Kick have belabored one another with hypotheses and equations innumerable. The struggle still rages, and we think that comment may well be deferred until next year.

In the line of assaying, Dr. Dewey has called attention to the revival of a method of directly determining silver in gold bullion, avoiding inquartation by alloying with cadmium, dissolving in nitric acid and titrating with standard sulphocyanide solution. This method, suggested by Balling and developed by Whitehead, had been lost sight of until revived at the San Francisco Mint, from which its use has been extended by the Mint Bureau.

Copper Metallurgy in 1914

Copper, more than any other metal, has been seriously affected by the European war. Many mines and some reduction plants are entirely closed, and mines and plants that are still operating are doing so under greatly reduced capacities, their output being about half the normal. At the beginning of the war an approach to a panic was noticeable among copper producers; all experimental work was discontinued, and betterments stopped. Gradually a feeling of confidence and security has been developing, and while the great foreign market for copper is still closed, yet with the establishment of equilibrium between production and domestic demand, a price has again been fixed which is very likely to be maintained.

Progress in copper metallurgy, during the past year, has been along the lines of the further application of flotation methods to the dressing of ores; of coal-dust firing to reverberatory smelting; increased activity in hydrometallurgical treatment, and the utilization of by-products.

By use of pulverized coal great economies in reverberatory smelting are accomplished. A greater tonnage of ore can be put through the furnace, a cheaper fuel can be used, a more complete combustion effected. Stoking and the handling of ash are eliminated. Furnaces of much greater size are possible; hence a more perfect separation of matte from slag is secured.

We are told of plans for building reverberatory furnaces with hearths 25 ft. by 175 ft. Coincident with the completion of these large reverberatory furnaces will be the blowing-out of blast furnaces, reverberatories being given the entire work of smelting all grades and kinds of ore. This means a marked increase in the percentage of copper on the charge, as concentration will be practiced to a much greater extent than formerly. By the adoption of oil flotation methods the losses in concentration, which occur mainly in the slime, will be very greatly reduced; and the cheap preliminary mechanical concentration, hitherto prohibited on first-class ores because of such losses, will be universally applied, except to self-fluxing ores. Another advantage of this plan will be that the large tonnage of limestone required under blast-furnace treatment of first-class, highly silicious ores, will be reduced to a minimum, for the concentrator will furnish a practically self-fluxing product and only enough lime will be added to the charge to produce a more desirable slag than the ferrous silicate furnished by the ore alone.

The practice in converting leady copper-matte, recently adopted at the Tooele plant of the Anaconda Copper Mining Company, is exceedingly interesting and may have a wide application. Under the old method of adding to the molten matte, in a basic-lined converter, sufficient silicious material to produce the standard slag, the fume passing to the bag-house was very corrosive and bags were destroyed to an extent that was practically prohibitive. The superintendent conceived the idea that a remedy might be found in converting in the absence of silica. This was expected to be accompanied by a building up of magnetite inside the lining, consequently limiting the life of each converter. Contrary to expectation the lining does not build up, and in addition a more complete elimination of lead and zinc is effected, together with the production of a fume which is non-corrosive to the filtering bags. To effect as complete elimination of lead and zinc as possible, the charge is over-blown, and as a result the basic slag is rich in copper. Both slag and matte are then transferred to other converters where, in contact with fresh copper matte, the final converter slag is brought down to a relatively low copper and silver content. This slag, of course, is re-treated as is usual with converter slags.

Efforts in the hydrometallurgical treatment of copper ores have been directed largely to methods of precipitation of the copper from solution. Preference seems to be in two directions: electrolytic and metallic iron precipitation. The former has many claims for first place, particularly because it furnishes a product that is at once commercial and requires at most only a furnace refining. The question of the production of foul solutions which complicate electrolytic precipitation in many cases is a serious one. The new plant at Chuquicamata is expected, according to recent reports, to produce electrolytic copper so cheaply that it can be placed on the European market at a price not exceeding 6 cents a pound.

Precipitation with metallic iron produces an impure cement copper, but this is of little moment when the leaching plant is connected with or near to a smelting plant. The amount of scrap iron is limited and a large plant will of necessity be compelled to seek some other source of metallic iron. Sponge-iron produced by reduction at relatively low temperatures, far below the melting point of iron, is an effective precipitant and will be largely used. Such iron can be made at a cost not greatly in excess of the cost of scrap iron, and with improved methods this cost may be still further lessened.

For some years a few smelters have been making arsenic in limited quantity, and much more would be made were there a market for the product. Cottrell fume-precipitation plants have been placed in successful operation at several smelteries and an exceptionally large one is planned for Anaconda. It is also planned to greatly increase the capacity of the Anaconda sulphuric acid plant, one unit of which was completed this year, so that not only will sufficient acid be produced for all hydrometallurgical needs, but also for the manufacture

of phosphate fertilizers. An attempt will be made also to save metals other than gold, silver, and copper, which have been the only ones heretofore receiving attention in copper smelteries. It has been found, further, that brick of a beautiful buff color can be made from tailings.

Status of Zinc Metallurgy in 1914

In reviewing the year 1914 in its relation to the metallurgy of zinc, the effects of the war greatly overshadow other considerations. The industry was not in a flourishing condition before the outbreak. The first half of 1914 had been a period of low metal-price, with small and uncertain margins for the zinc smelters. This was due in general to the business depression, and in particular to an increasing metal stock with irregular demand; to an uncertain ore supply and the stagnation in the iron and steel industry. When war was added to the existing burdens and uncertainties, managers and executive committees found it necessary to give almost undivided attention to finances, metal-price fluctuations, changing ore supplies and plant economies. There was so wide a disagreement as to the probable market position of the metal that metallurgical experiments and improvements were quite generally restricted, deferred or abandoned. Until the end of the war can actually be seen, it seems likely that, although better metal prices may obtain, and the situation look brighter for both miner and smelter, not much new work will be started.

In the smelting or metal-producing end of the industry, there have been, nevertheless, several interesting developments during the year. One was the tendency of the sponsors of those electric and electrolytic processes which have had more or less successful laboratory trials, to locate their first small commercial plants near the Mississippi River power supply. Although one of the chief aims and reasons for these processes—elimination of freight charges on low-grade ore—is thus ignored, there are other factors which outweigh this consideration, at least for these trial plants. They are cheap power, fuel, labor and supplies; a variety of ores and furnace products from which to choose; good transportation and near-by markets for products.

This tendency is being opposed by an active effort from a new source. The hydroelectric power companies of the Western mining states, in an attempt to equalize their irregular power load and to build up new business in mining regions at present inactive, have not only offered direct inducements to mining companies known to be considering electrolytic processes, but have sent into the field a staff of their own experts to work on processes and methods supposed to be suitable. This may perhaps be termed a flank attack on the complex-ore situation, and at least offers possibilities in the way of securing the best available apparatus, in marketing some by-products, and even in providing some financial assistance.

No radical changes in the retort-smelting of zinc ores can be chronicled. The year's record is again one of many small improvements in details of construction and operation.

Several of the American zinc smelting companies are now regularly marketing zinc dust which, as a precipitant of gold and silver in the cyanide process, is steadily replacing zinc shavings made from sheet metal. Zinc dust has heretofore come largely from Germany, the imported dust being considered more desirable than the domestic product on account of greater uniformity, both physical and chemical. Having had the market for this material practically forced on them, American managers quickly arranged to supply it and are rapidly learning to turn out a satisfactory product.

Improvements in methods of handling retort residues at the zinc furnaces have brought about such an increased commercial saving of gold, silver, lead, and copper from Western mixed ores, and have made results so regular and dependable, that such ores are now commonly purchased under sliding-scale schedules providing payment for all valuable metals contained. This has already made profitable several Western mines heretofore operated at a loss or not at all.

The fact is well known that not only do the residues from retort furnaces carry most of the gold, silver, lead, and copper in shape for recovery by lead or copper smelting, but so also do the residues from zinc-oxide furnaces. Many proposals to use the oxide furnace as a preliminary igneous concentrator have been made, and trials have proved that it is metallurgically possible. Economic factors, however, have made it questionable whether such processes will succeed if placed near the mines, where they are most needed. It would seem as though there must be favored locations where such methods might succeed. A beginning was made at Leadville during the year, and some progress reported; but at least another year will be necessary to determine the real possibilities of the plant.

In the mining and milling end of the industry, in which the ore producer is more directly interested, and seems likely to be for some time to come, there is not much positive and completed improvement to record. Wet concentration has advanced only in minor details. Some new work of interest has been done with dry concentration, but results cannot be said to be final. Magnetic and electrostatic separation hold their own in a field that does not seem to widen much. Chemical methods made little progress except along electrochemical lines. The work begun in chlorination in the Coeur D'Alenes is claimed to be very promising, but success is not yet a certainty.

The one really active process is flotation, and here the interest and work are widespread. It is unfortunate that the patent situation is so unsettled, because many really important discoveries are not being given publicity. This is particularly true with regard to selective methods aiming at separation among the several sulphide minerals. When once it has been definitely settled how far the claimed fundamental patents extend over the industry, it is certain that progress will be much more rapid. Enough is known now to make it certain that flotation can be made selective, but the degree of success and the methods to be employed will not be revealed for some time to come. While this is truly un-

fortunate from the standpoint of the mine operator, it nevertheless points decisively to the fact that flotation as a whole is by far the most important, inclusive and promising of any of the preliminary methods; that it is getting widespread and competent attention, and is certain to attain extensive application.

The Steel Trade's Poor Year

The year just ended has been the worst, from a commercial standpoint, that the steel trade has passed through since 1898, the last year of the great industrial depression. Production has been exceptionally small, about 60 per cent of capacity, while prices realized have been at the lowest average level since 1898.

The steel trade is distinguished from many other industries by the facility with which it makes remarkable records. It is, as Andrew Carnegie used to remark, either a prince or a pauper, though why he should be the man to say so is not so easy to fathom. Perhaps the one aspect mentioned represents his experience and the other his observation. There are some good reasons why the steel trade should experience violent fluctuations. One reason commonly assigned is that its products go very largely into permanent construction, but the volume of construction work in general hardly exhibits the wide variations that are observed in steel making activity, and the proportion of steel output that passes into current daily consumption, as in tin plate, for instance, is quite large.

The principal cause of the fluctuations in the steel trade is that stocks are carried by buyers and are not carried by sellers. The buyer is speculative to an extent. He anticipates his requirements when he thinks the market is going to advance and thus he helps to cause the advance. He curtails his stocks when he observes the market is declining and thus he encourages the decline. The buyer's conduct by no means represents pure speculation, for the nature of steel mill operations is such that when orders are plentiful long runs on a given size are specified for the individual mill and deliveries are made slow, while when orders are light rolls are changed or reset for the small specification and shipments are made promptly. As the mills grow busier the buyer must increase his stocks, as he can depend less upon the mill for quick shipment of the sizes and descriptions of steel he may need, while as mill activity decreases the reverse is the case. The average stocks of steel in the country are large, running well into the millions of tons and distributed in many quarters from the large jobbers' warehouses down to the country blacksmith, and the fluctuations from large stocks to very small stocks are necessarily counted in the millions.

There are other industries in which buyers carry stocks in widely varying amounts, but in such industries there is usually the opportunity for the producer also to carry stocks upon occasion. Copper is a highly speculative metal and buyers carry large or small stocks upon occasion, but the copper producers can readily carry stocks themselves, continuing production at an economical pace and withholding the product from the market. The steel manufacturer cannot do this, except in a few instances. Wire products, nails, fence, etc., can be stocked, and some descriptions of tubular goods can be stocked to an extent. Tin plate formerly could be, but sizes have been so multiplied that stocking is risky. Rails, bars, plates and structural shapes are not stocked, there being no standard sizes and specifications to which the mill can work to advantage. In the case of sizes that are common the cost of storage and rehandling would be unreasonably large.

The extreme leanness of the past year in the steel trade was due to a combination of circumstances. A rhythm of ups and downs had been established, but special conditions operated to make the trough in the curve particularly deep and wide. After the period of great activity ending late in 1907 the country found itself with large stocks, and a year of very light production, but with prices sustained by a common purpose among sellers, was needed for liquidation. In 1909 occurred a great wave of buying and the country restocked itself in the second half of that year and the fore part of the next, liquidating in turn thereafter. In 1912 the buying movement was repeated, though with less enthusiasm, the stocking up process continuing into 1913. At the beginning of 1914 the liquidation in stocks was not entirely completed, though probably nearly so. The trade was due, apparently, for an upward swing had not special conditions intervened. The first was the unwillingness or inability of the railroads to make their usual purchases, insisting that they needed an advance in freight rates to enable them to buy, and month by month during the first seven of the year the market waited for "the rate decision." Not only did the railroads not buy, but other buyers felt there was no occasion to purchase when the railroads were not figuring in the situation. The long expected rate decision, favorable by less than one-half the demands made, was announced on August 1 and fell absolutely flat, for the world was then experiencing the greatest shock in its history. The war then prostrated the steel industry afresh.

By the ordinary rhythm an important revival in the steel trade is months overdue, and the barriers to at least a moderate recovery are removed. By the recent reopening of the freight rate case the railroads are given almost all they originally demanded. The new banking and currency system makes it that financial troubles are largely past. The history of wars is that their worst effects in trade disruption are felt at the start, and the influence of the present war should now be decreasing. That humanity must pay a tremendous bill for this war is beyond question, but the payment will be made over a long period of years, not while the war is in progress.

As a matter of fact the steel trade has already started to experience at least a minor recovery. Beginning with a change in sentiment early in November the movement worked into a stage of heavier buying in December and at the opening of the new year the trend of prices in some commodities at least is distinctly upward.

Electro-Analysis of Nickel

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I notice in your November issue an abstract of an American Electrochemical Society paper by Dr. W. Judson Marsh on the electro-analysis of nickel. The methods described have been in use at this laboratory for two years and found to give excellent results. The application of the base metal gauze was described in a paper from this laboratory published in *Metallurgical & Chemical Engineering*, February, 1914. We used a 100-mesh brass gauze, for the reason that a finer mesh can be obtained in brass gauze than in copper. This gave successful results in cases of zinc, nickel, copper, without any rotation. Currents of three and four amperes were employed at first and were cut at the end of the electrolysis to 1 to ¾ ampere.

The Action of Fluorspar on Basic Open-Hearth Slags

To the Editor of Metallurgical & Chemical Engineering.

Sir:—Any one familiar with basic open-hearth work knows that fluorspar CaF_2 is a very efficient agent in making the basic slag more fluid. Different theories have been advanced as to what reactions take place to give the above result, but none have appeared very satisfactory.

With fluorspar we add calcium which, as the oxide would give us a more basic slag, hence one more thick. We also add fluorine which we would expect to unite with silicon and pass off as a gas silicon fluoride. This removal of silicon would also made the slag more basic, hence thicker. However, we know that the slag is made thin to a very great extent when small percentages of fluorspar are added. The amount of fluorspar necessary being very small, the actual addition of a little calcium and removal of a little silicon would really give no apparent results.

The remarkable fluidity conferred by a small amount of fluorspar being added to a molten slag has suggested to me that the reaction may be a catalytic one; i.e. the fluorspar may be only an agent.

Reactions which I believe may account for the thinning of a basic slag are shown in the following two simple equations, although no doubt more complex reactions do take place.

Silica reacts with fluorspar to yield silicon fluoride and calcium silicate

$$3SiO_2 + 2CaF_2 = SiF_4 + 2CaSiO \qquad (1)$$

Lime reacts with silicon fluoride to yield fluorspar and calcium silicate.

$$3CaO + SiF_4 = 2CaF_2 + CaSiO \qquad (2)$$

In equation No. 1 the fluorspar reacts with the silica in the slag, giving us silicon fluoride (a gas) and calcium silicate, a fusible slag. Part of the silicon fluoride will escape but a greater part will react with the lime, giving us our fluorspar again and more calcium silicate, the fusible slag. This newly formed fluorspar will react with more silica as in equation No. 1 and the circle is repeated until all the silicon, fluoride gas has escaped. In each reaction some silicate of calcium is formed which is a slag with a low melting point, and the fluorspar has only been an agent to unite the silica and lime, either of which alone is fused with difficulty.

Is There a Complex-Ore Problem?

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I have been too busy to reply sooner to Mr. Ionides' letter in your November issue, while this letter has also been delayed by the burning of bridges on the Nacozari Railroad.

I did not assume that the ore mentioned by Mr. Ionides was mined at Broken Hill, Australia. I cannot see what grounds he has for making that assertion. I merely stated that its zinc, lead and silver contents were about the same as that of the ore now being mined at Broken Hill. Even if this ore contains (as he says) a large percentage of pyrite (which the Broken Hill ore does not), I cannot see why that should "render it wholly unadapted to ordinary mechanical concentration." Is it not possible to do as was done at Broken Hill before the flotation process was introduced (as mentioned in a previous letter of mine)? That is to say, could not the lead and some of the silver be saved and the tailings stacked pending discovery of a suitable process? Would not that be better than selling the ore to a smelter and not only losing the zinc but paying a penalty on it?

I thank Mr. Ionides for his offer to put me in direct communication with the owner of this property and gladly avail myself of his offer.

Regarding the extraction at the Broken Hill South Mine during the latter half of 1913, I agree, after studying the figures supplied by Mr. Ionides from the *Australian Mining Standard* (which I had not previously seen), that, as the metal contents of this zinc *tailing* are not in a marketable form, they should not have been included in reckoning up the total extraction. The correct way would be to include the percentage of original contents for ore as contained in the zinc *concentrate* produced by the Amalgamated Zinc Company from the zinc tailing sold to them by the Broken Hill South Co., plus the percentage recovered in the concentrate produced from the slime by the new slime concentrating plant, which is a modification of the Minerals Separation process. I still maintain that a high extraction is obtained at Broken Hill from ore containing silver, lead and zinc—higher probably than at any other mining center—and that it is improving every year.

Mr. Ionides has a good deal to say about "commercial saving" and, of course, I agree that it is the basis of successful mining, but I understood the subject of our argument was mill extraction. The fact that the Broken Hill South Co. sells its zinc tailing to the Amalgamated Zinc Co. and only received about 5 per cent of its gross value in return in no way disproves my statement. If Mr. Ionides will study the figures of the Zinc Corporation, Sulphide Corporation, and Broken Hill Proprietary Co., which themselves treat the zinc tailing produced in their lead concentrating mills, he will see that the "commercial saving" of the zinc is much greater than 5 per cent.

Regarding the question of making a high grade or marketable concentrate from lead or copper slime, this is being done at Broken Hill (with lead slime) by flotation processes with which I am acquainted, and also I understand in Missouri, and I know of a place not 1000 miles from here (to quote one instance only) where they are making a concentrate containing 23 per cent copper from slime containing only 1.5 per cent copper. One of the flotation processes is used. Most of the copper is in the form of chalcopyrite. On a purely chalcocite slime it is possible to make a much higher-grade concentrate.

I have just come across the following figures relating to the operations of the Zinc Corporation at Broken Hill during 1913: "The zinc concentrator treated 350,120 tons of tailing assaying 14.16 per cent zinc, 5.95 oz. silver and 5.7 per cent lead, for a yield of 102,850 tons of flotation concentrate, assaying 44.2 per cent zinc, 12.1 oz. silver and 12.5 per cent lead. The re-treatment of this product by tabling and the Horwood process combined yielded:

	Zinc, %	Silver, %	Lead, %
81,820 tons zinc concentrate assaying.....	47.1	10.5	7.7
3,082 tons Horwood zinc concentrate assaying.	47.3	15.3	9.5
12,623 tons lead concentrate assaying.....	15.4	31.8	55.4
1,498 tons Horwood lead concentrate assaying.	18.8	35.3	32.9
3,442 tons zinc slime for re-treatment.....	36.7	24.5	16.2

"The sterling value of these products (except the last) was 72 shillings and eight pence per ton of reflotation concentrate, the enhancement, as the result of re-treatment, being £106,985. As the cost of retreatment amounted to £25,035, the profit was £81,950.

"The cost of treatment of tailings in the zinc concentrator (including regrinding) averaged 10 shillings and 2 pence per ton (say $2.44), of which 18 cents per ton represents the cost of operating the Horwood plant."

The following extract from the *Barrier Miner*, published at Broken Hill, may be of interest:

"Tests made on Tasmanian ores show that 85 to 90 per cent of the zinc can be recovered as a high-grade zinc concentrate, assaying 57 per cent zinc, while the same percentage of the lead contents can be recovered in a separate product along with the iron contents of the ore (in a form which makes the material practically self-fluxing), accompanied by also 75 to 80 per cent of the total silver contents of the ore and about 90 per cent of the gold contents."

Do any of your readers know of any place in America where anything approaching this is being done?

Nacozari, Sonora, Mexico. W. MOTHERWELL.

Grinding Ore for Cyanidation; A Suggested Modification for All Sliming Practice.

To the Editor of Metallurgical & Chemical Engineering:

SIR:—I wonder why we have not heard more about the system of classification of pulp and solution before tube-milling in the all-sliming plants, as suggested by Mr. Pentland in your October issue. Even for obtaining higher-grade solutions for precipitation from the first thickener previous to final agitation and counter-current washing, if not gaining ultimately higher *indicated* extraction.

The two and three-stage crushing plants present unique means of classifying pulps as Mr. Pentland has outlined, and it seems that cyanide metallurgists are slow to perceive and grasp the opportunity where they are not using the counter-current decantation, and depend on filter displacement. What is true in one case, may be adverse in another, but where a large tonnage of solution is used, as in the decantation system, these points undoubtedly should be investigated as otherwise.

I will cite an instance in Arizona, a plant I operated some three years ago, where radical changes were necessary along these lines.

We were confronted by numerous problems. The main apparatus was well enough arranged, but the pulp flow and solution classification did not prove efficient for actual recovery. The indicated dissolution of gold values was simple enough, but it was necessary to make the system more continuous and deliver less dissolved values to the filter.

The crushed ore and solution as delivered and discharged from a Chilean mill, passed a 16-mesh screen to an Akins classifier, where the sand was separated from the slime (24 per cent), and conveyed direct to the 5/22 tube-mill. The slime and excess solution flowed to the first thickener. The gold values were principally in the sand material, and about 60 per cent of the extraction took place in the tube-mill circuit. Instead of returning the tube discharge (1 to 1) to the Akins, a deep cone was installed to receive this partly reground pulp for returning the unground sand to the tube. The density of this pulp was too thick for proper classification. Therefore, as head room premitted it, a portion of the slime and excess solution was tapped from the end and bottom of the Akins to dilute the cone feed, maintaining an overflow of 2½ to 1 ratio. This finished product passed direct to No. 1 agitator, being of the proper density for agitation, where most of the remaining values went into solution. This pulp, after partial treatment, subsequently passed continuously to No. 1 thickener and the clear overflow carried away 80 per cent of the already dissolved values, or 60 per cent of the original ore values plus assay of ongoing mill solution, to precipitation.

The discharge from No. 1 thickener (sand and slime 1 to 1), bypassed No. 1 agitator to No. 2 agitator. Thus the sand (150 mesh) obtained longer treatment while the slime received one-half the treatment originally planned. After installing these improvements the mill tonnage was materially increased. The extra sand treatment enabled less grinding, and the only reason this change was made in the upper part of the plant was to produce high-grade solution for precipitation from No. 1 thickener.

The plant had only two thickeners, one before agitation and the other following to thicken for filtration.

Our ultimate object in view was to obtain as low a grade of pulp as possible for filtration. The overflow from the No. 2 thickener originally passed to precipitation and then to the head of the mill. This was discontinued and in changing the system, the dilute filtration solution was united with the barren precipitated solution, delivered to No. 2 thickener and discharged under the surface of overflow level, below the inflow of pulp from the agitators. In this manner the solids settled in a more barren solution than otherwise. When the thickener is large enough, the scheme of upward displacement works ideally on tube-mill product, and we gained the desired results of delivering a practically barren pulp to the filter.

To overcome the necessary headroom required, and supplying a thicker flow to the tube-mill, I would suggest it better to use the cone for the first classification, providing a Dorr or Akins classifier will separate fine sand from course economically of pulp with the density of 1.250 finished product; suitable for direct agitation. Further in this arrangement and in some cases I suggest a large thickener cone (with goose neck), for sluffing off part of the first crushing solution from the first classifier dilute overflow. This will result in richer and less solution for precipitation, where much solution is used in the first crushing, and low grade. Likewise the discharge of No. 1 thickener would be slightly richer using the sluffing-off tank, but this solution could pass to No. 2 thickener and perhaps perform its duty to better advantage.

Of course, these additions require more headroom, or returning to the old system of elevating separately the tube-mill discharge in returning to the circuit.

In many cases the first slime produced is the more refractory part of the ore, causing higher cyanide consumption, difficult to settle and filter, often requiring more solution ratio and longer treatment, whereas the difficulty in the sand treatment is overcome by the fine grinding. However, in a direct cyanide plant the sands portion from the first crushing generally assays the higher, or contains the larger percentage of original values, and my experience has been that the greater ex-

traction takes place during the fine grinding and the first eight to twelve hours air agitation of the pulp of more dilute consistency. Where the extraction has been poor in the tube circuit and the chemical consumption high, with an six to eight-hour agitation in a restandardized solution and more dilute pulp, directly after the gold or silver has been cleaned by the grinding process, I find a high percentage of extraction takes place.

The only difficulty experienced with the above procedure was the accumulation of coarse sand in the first agitator, but in our case the extraction was better, since this product received longer treatment. We would run continuously for a number of days, and then partly empty the agitator for a fresh start. In treating 150-mesh sands by agitation where the colloidal or first slime has been removed, a shallow tank with numerous air lifts, such as the Parral, would insure less short-circuiting or concentration of the coarse sand. The material treated in a low tank with numerous lifts has a chance to circulate up and down and around the entire tank before passing out. The Dorr agitator would undoubtedly guarantee less danger of this segregation than would the ordinary Pachuca.

Tube-Milling Tonnage Calculation and Notes on Tube-Milling.

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I have read with much interest Mr. Noel Cunningham's article on calculating tube-mill tonnage, appearing on page 22 of this issue, and have carefully studied his method of calculation and the equation obtained. Mr. Cunningham has handled the subject in a novel manner, and has presented something in which all operators will be interested. A study of his calculation leads to some interesting speculation on the general subject of tube-milling, relating to current practice in all-slime cyanide practice.

In my opinion Mr. Cunningham's equation is correct for certain ideal conditions which, however, are not attained in practice. The necessary ideal conditions would be that the total tonnage be ground to minus 200-mesh, or, in other words, that the quantity of minus 200-mesh pulp overflowing the classifier be equivalent to the total battery tonnage. Of course this is not the case, as there is always a percentage of plus 200-mesh material in the classifier overflow.

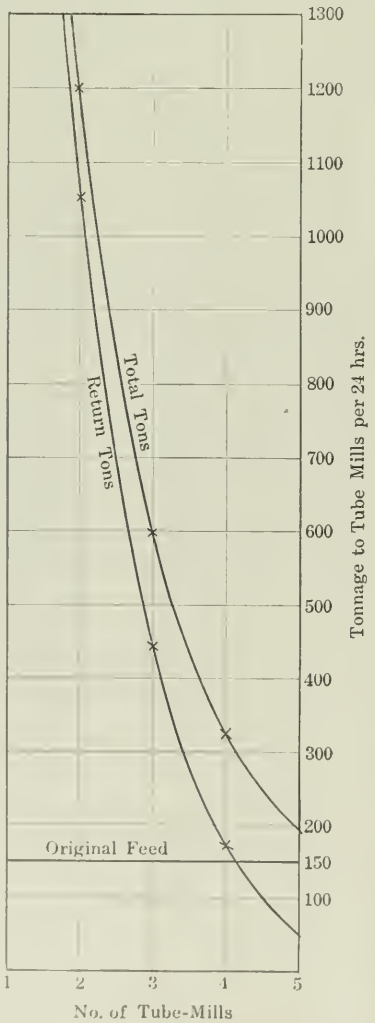

FIG. 1—SHOWING ACCUMULATION IN TUBE FEED DUE TO INSUFFICIENT NUMBER OF TUBE-MILLS

In order to insure having the classifier overflow all ground to minus 200-mesh, it would be necessary to have sufficient tube-mill capacity to grind all the battery oversize to this mesh, and, as it now seems to me, do this in one passage of the pulp through the tubes. Of course, if this were the case, there would be no need of running the tube-mills in closed circuit with classifiers.

All this leads to some interesting speculations on current tube-mill practice in cyaniding, with particular reference to (1) the conditions most favorable for obtaining the maximum fine grinding in a tube-mill; (2) cumulative effect of returning to a tube-mill a part of its discharge that has not been ground to the desired degree of fineness; and (3) the consequent propriety or impropriety of the "closed circuit." Mr. Pentland has touched on some of these points in his article on tube-milling, published in your December issue, page 750, raising some of the same questions from the viewpoint of correct moisture content of tube-mill pulp.

If a tube-mill is unable to crush the entire oversize from its quota of stamps to minus 200-mesh, with one passage of the pulp through the mill, there will be a return of oversize from the classifier. This, in time, increases the load on the tube which, in turn, produces a diminishing percentage of minus 200-mesh material and an increasing percentage of oversize. If a certain amount of this oversize is allowed to overflow the classifier, equilibrium will be established; but if an attempt is made to hold the classifier oversize at minus 200-mesh, the accumulation in the tube-mill will ultimately reach a point where the machine will do little or no work. I am sure all cyanide operators have had such an experience.

Recently there was published[1] a series of tables on tube-milling, some of which are pertinent to this discussion. One of them, given below, bears on the accumulation of oversize under closed-circuit conditions, and the number of tubes required to perform a certain duty.

Table I.

Relation of Feed per Mill to Tonnage of Return Feed

Tube-Mills Operating	Tons Dry Sand per Day—Feed per Mill	Total Feed to All Mills	Total Return Feed
5	40	200	50
4	80	320	170
3	200	600	450
2	600	1200	1050

Note.—In each case the total initial feed of concentrator tailings passing to the tube-mills was 150 dry tons per 24 hours.

A study of these figures, which are also plotted as a curve in Fig. 1, shows the accumulation in tube-mill feed due to the increasing quantity returned. When this accumulation begins to reach serious proportions, it naturally shows itself in the screen analysis of the classifier overflow; that is, by an increasing amount of plus 200-mesh material. Many cyanide operators (I have done the same thing in the past) will attempt to adjust this by changing the baffle on the classifier or by diluting the battery pulp, so that only the finest material will overflow the classifier. On second thought, however, it will appear that this merely makes matters worse and allows a greater accumulation before the inevitable equilibrium is again established by the overflow of more plus 200-mesh material from the classifier. When such a condition does arise there is no way of adjusting the classifier to prevent it, and the only solution lies in increasing tube-mill capacity. For this reason I consider any adjustment of the classifier as utterly useless. That machine cannot be made to control a condition that is created in the tube-mill and for which the latter is responsible.

This brings up the matter of closed circuit, for if we

[1] *Eng. & Min. Jnl.*, Sept. 2, 1914.

increase tube-mill capacity to a point where it will grind the entire oversize as desired, we have then reached a point where there is no need of returning the discharge to the classifier, as the product from the tube-mill will then be practically the same as the classifier overflow.

From the foregoing it can be seen that in a plant curve in Fig. 2 the data from these tables as relating to the minus 200-mesh pulp produced, except that I have shown actual tons instead of percentages as originally given. This curve shows that, with an increase in the tonnage fed to the tube, the actual *quantity* of material ground to minus 200-mesh increases.

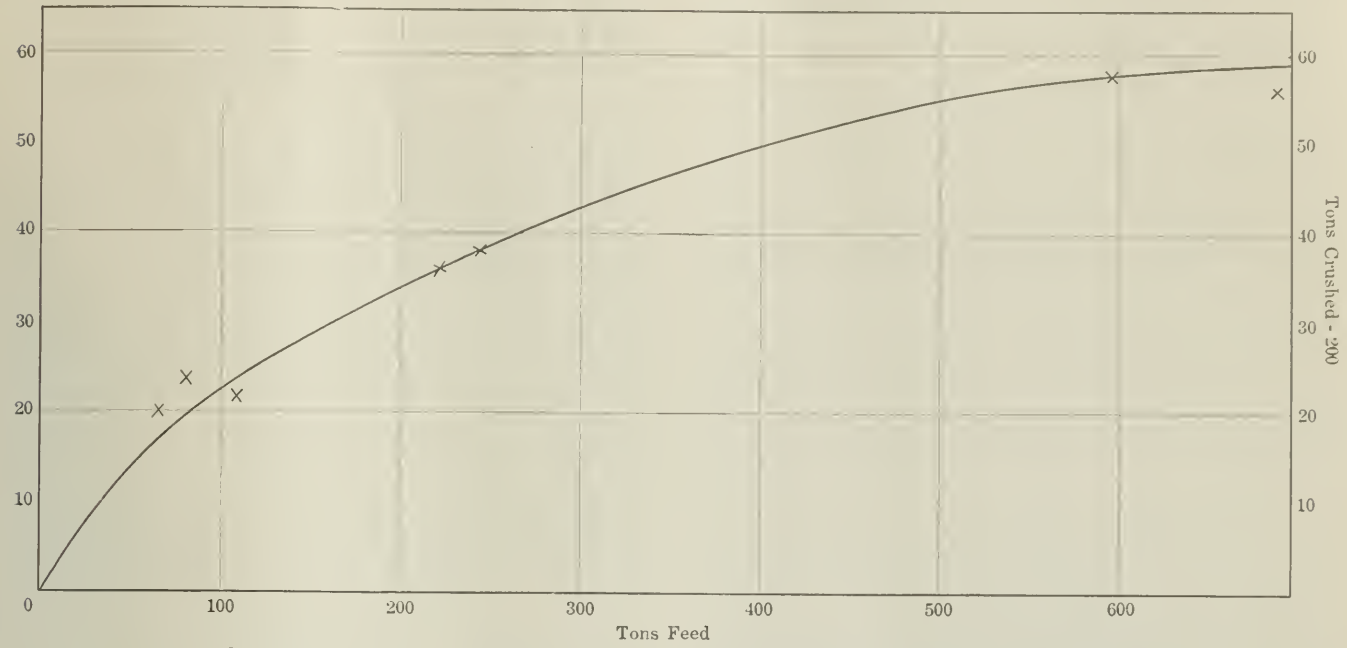

FIG. 2—TONS CRUSHED TO MINUS 200-MESH IN TUBE-MILLS AT VARIOUS RATES OF FEED

containing, say, two tube-mills in parallel, neither of which will handle its tonnage so that the product does not need classifying, it may be possible, by putting the tube-mills in series, to obtain this result. In fact, this was proved to be the case at the Liberty Bell mill, where two tube-mills in series gave a finer product than three tube-mills in parallel in closed circuit.

Other tables appearing in the source already mentioned show the effect on the grinding obtained in tube-mills by varying the tonnage fed. I have plotted as a

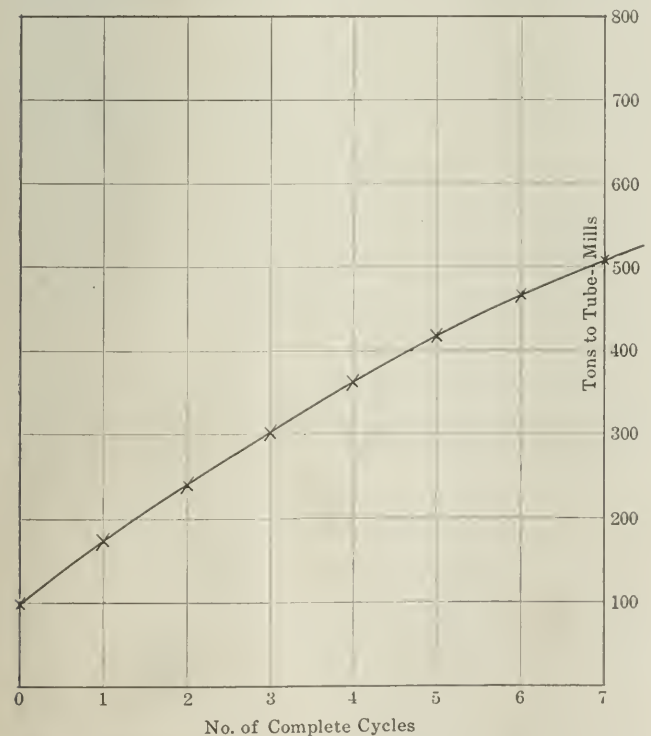

FIG. 3—SHOWING ACCUMULATION OF PULP IN TUBE-MILL CIRCUIT WITH 100 TONS PER CYCLE OF INITIAL FEED

But the *percentages* of that product is steadily decreasing, which shows that the feed is increasing faster than it is ground to the desired degree of fineness. In other words, the *per cent* of minus 200-mesh material produced is approaching zero as the feed increases, and will ultimately reach a point where none of that product will be made. The following table gives the figures from which the curve is plotted.

TABLE II

Effect of Varying Tonnage in Tube-Mills

Tons feed 24 hours	67	80	109	217	239	570	693
Per cent minus 200-mesh in discharge	30.03	30.15	20.04	16.56	16.00	10.28	8.09
Tons minus 200-mesh in discharge	20.12	24.10	21.84	35.93	38.24	58.59	56.06

The curve given in Fig. 3, which is derived from the data afforded by the curve in Fig. 2, also has a bearing on the subject of accumulation. Suppose we arbitrarily consider the flow of pulp as intermittent or occurring in cycles, and assume 100 tons of oversize coming from the batteries to the classifier in each cycle. Then in the initial cycle we will deliver 100 tons to the tube-mill, and of this (see Fig. 2) 23 tons is ground to minus 200-mesh, leaving 67 tons of oversize to be added to the next 100 tons of original feed, making a total of 167 tons in the second cycle. By continuing this calculation we get the results plotted in Fig. 3, showing the accumulation in the tube-mill circuit. The only way of preventing this accumulation is to provide sufficient tube-mill capacity to grind the battery oversize in one passage through the tube, whereupon the curve of Fig. 3 would become a horizontal line. That this accumulation does not occur in practice is due to the fact that the classifier acts as an equalizer, maintaining equilibrium by overflow plus 200-mesh material.

The figures given in these tables and curves are not intended to represent general tube-milling practice, and the actual data given will vary widely from similar data on other ores and with other mills, but they illustrate the point I am trying to make.

The general accumulation of ore in the tube-mill circuit is enormous, and is not generally realized by tube-mill operators. As shown in Table I, where two tube-mills were used they were ultimately grinding every twenty-four hours seven times the tonnage of the batteries; and I think I can safely say that this is no exception, as the tonnage usually ground in tube-mills is tremendous as compared with the total tonnage coming from the stamps.

While this discussion has not all been pertinent to Mr. Cunningham's article, it has been suggested by it and by Mr. Pentland's notes on tube-milling for all-slime cyanide practice. The meat of the entire matter resolves itself into the fact that with a certain design of classifier, tube-mill and stamps, working on a certain ore, the degree of fineness of classifier overflow becomes a constant when equilibrium has been established. Absolutely the only way to obtain a larger percentage of minus 200-mesh material in the final product is to increase tube-mill capacity, in which case the closed circuit will not be needed. To put this condition into a formula would require a separate formula for each tube-mill, and a constant due to the ease with which the ore is ground.

Justin H. Haynes.

Denver, Colo.

The Western Metallurgical Field

Optimism in the Mining and Metallurgical Industry

We hold to optimism because we know that temporary depression is ultimately compensated by activity and prosperity. There are growing evidences that we have passed the period of shock following the declaration of war in Europe, and that we are readjusting ourselves to the new conditions forced upon us. In the West there is a feeling that capital is going to seek investment in mining and metallurgical enterprises, and this sentiment also holds in some quarters of the East, according to reports of engineers who have recently investigated the situation.

At the Phoenix, Ariz., meeting of the American Mining Congress, held last month, Mr. George Otis Smith, director of the United States Geological Survey, expressed the spirit of optimism which is now prevailing. "Europe's war finds its echo in America's industry. Evidence of business betterment is before us on every hand, and the reasons for optimism are many. Foreign orders have started factory operation which at once tends to relieve the stagnation in the steam-coal trade; the steel situation has turned from serious depression to rapid improvement, and the whole mineral industry may soon expect to share in this general business improvement. To-day the financial horizon is so nearly cloudless that the prophets of bad weather have little upon which to base their predictions. Coming down to bottom facts, the United States will profit by the European war only as the nation makes larger and wiser use of its mineral resources."

Heavy Exports of Zinc

Figures compiled by the bureau of foreign and domestic commerce of the Department of Commerce, show that the exports of domestic zinc during September, October and November exceeded the total for the seven-year period ended June 30, 1914. The exports during this period rose to the unprecedented total of 65,504,574 lb., valued $4,443,381, as compared with 1,346,877 lb. valued at $80,756 in the corresponding period of 1913. The year 1897 was the former high-record year in zinc exports, when the total was 35,869,987 lb. The recent large exports of zinc were for England, Scotland, France, Italy, Denmark, British Africa and Australia. The exportation during the three months above mentioned was about 10 per cent of the domestic production which, in 1912, amounted to 647,814,000 lb.

Mackay School of Mines

The Mackay School of Mines of the University of Nevada has taken steps to increase its usefulness to the state by offering a short course in prospecting. It is expected that attendance on the lectures to be given will have the effect of making prospecting more intelligent and efficient, and consequently contribute to the advancement of mining in Nevada. The course will be offered for four weeks during February, 1915, a nominal fee of $5 being charged. Instruction will be given in excavation of earth and rock, prospecting, mineralogy, geology of mineral deposits, assaying, gas engines, first aid and mining law.

The metallurgical laboratory of the Mackay School of Mines is well equipped for instruction to supplement lectures given in the classroom. The recent addition of a small filter-press to the cyanide equipment makes that department practically complete. It is the policy of this school to use small-size machinery in its laboratory work, rather than standard machines that are too large for frequent use by students. Equipment for metallography and mineralography is now available for the microscopic study of metals and minerals, whereby knowledge is gained that is of use in determining the methods of treatment to which ores are amenable.

Molybdenum in Colorado

The Primos Chemical Co., which already is engaged in mining and treating tungsten and vanadium ores in Colorado, has recently become interested in property at Georgetown, Col., where molybdenum ore carrying some gold and silver has been developed. The company has been engaged in making some surface improvements and underground developments, with the probable intention of erecting a treatment plant of some kind when metallurgical tests have been completed. It is likely that nothing more than some form of concentration will be attempted at the mine, leaving reduction work to be done at an Eastern point.

New Cyanide Mill for Pittsburgh-Dolores Mining Co.

The Pittsburgh-Dolores Mining Company is remodeling the old Rockland mill, situated 27 miles from Yerington, Nev., into a modern cyanide plant. The former mill was erected as a leaching plant, but was not a success and has not been operated for seven years. Preliminary tests on the ore indicated that an extraction of about 95 per cent could be obtained from $12 ore by grinding to 100-mesh and cyaniding. The old, coarse-crushing equipment was therefore supplemented by a 5-ft. x 18-ft. tube-mill, which will grind in closed circuit with a Dorr classifier.

The new mill will have a daily capacity of 60 tons and will adopt continuous decantation. In the old leaching equipment there were five steel tanks, 30 ft. in diameter by 5 ft. in depth. These will be converted into Dorr continuous thickeners. The tanks are shallow, but on account of the large settling area afforded for the tonnage to be treated, and the rapid rate of settlement of the ore, it has been considered safe to commence operations with shallow tanks. Provision has been made, however, for deepening the tanks to 8 or 10 ft. if necessary, by equipping the thickeners with long driving shafts. It may be that 5 ft. will be sufficient depth for such quick-settling material, and that a low-moisture discharge will be induced by the coarse sand packing near the point of discharge.

As the old leaching vats were arranged on the same

level, they will not be changed in the remodeled plant. This will make it impossible to get gravity flow of solution through the continuous decantation system in the preferred manner, and in order to secure thorough mixing of the thickened slime and decanted solution passing to the various thickeners, mixing cones will be installed. The mixture discharged from these cones will be elevated to the thickeners by air-lifts which will be regulated by floats within the cones, rigidly connected with the valves on the air line.

Agitation will be continuous in three Dorr agitators, 22 ft. in diameter and 19 ft. deep. Compressed air will be delivered by a 12-in. x 12-in. compressor run by a 10-hp motor. This will give 150 cu. ft. of air at 20-lb. pressure, which will be used for agitation and air-lifting. The manner of connecting the agitators for continuous work is shown in the sketch, Fig. 1. The adjustable transfer pipe makes it possible to draw off pulp of uniform density and prevent classification within the agitators. A feature of the plant is the small power requirement for the continuous decantation department.

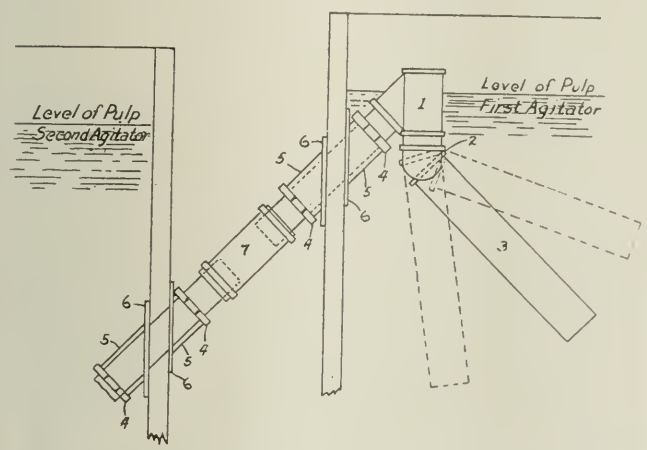

FIG. 1—CONNECTIONS OF DORR AGITATORS IN SERIES

1 Standard C. I. "Y" Bend. 2 Double E II. 3 Adjustable Transfer Pipe. 4 Lock Nuts. 5 C. I. Bevel Hollow Washers to be pressed against gaskets (6) by lock nuts (4). 6 Gaskets. 7 Flexible Rubber-Tube connection.

A 10-hp motor is provided for the operation of three agitators, five thickeners, two solution pumps and five diaphragm pumps. Mr. E. J. Schrader, of Yerington, Nev., is manager for the company.

Normal Conditions Exist in Cobalt

With the resumption of operations at the Buffalo low-grade mill on Dec. 7, mining and milling conditions at Cobalt, Ontario, are about the same as before the declaration of war. The Buffalo company suspended operations four months ago, starting work in the mine after a few weeks, but doing no milling until the date given above. The high-grade mill is still closed, but as it handles concentrates from the low-grade mill, it is likely that it too will be started soon. Weekly shipments from Cobalt continue to increase as the aspect of the silver market improves.

The Cyanide Situation

Speaking before the Mining and Metallurgical Society of America, at a meeting of the New York Section, Mr. Otto Ruhl, of Roessler & Hasslacher, said recently that his firm began the manufacture of potassium cyanide at Perth Amboy, N. J., in 1890. The old method of using potassium ferrocyanide was employed. The first sales were not for gold extraction, but for fumigation of trees. Seven years after beginning production, the first carload was sold at 45 cents per pound. When the Dingley tariff came into effect in 1897, the rate of duty on cyanide was reduced from 25 per cent to 12½ per cent *ad valorem*, and the domestic production of cyanide was ended until 1902. In that year Roessler & Hasslacher took up the manufacture of sodium cyanide by the synthetic process of Hamilton Y. Castner, an American chemist. "It took fully ten years to reach the high standard of sodium cyanide which we are now producing, equivalent to 128 per cent to 130 per cent potassium cyanide, now universally recognized as the only proper material for electroplating, fumigation and gold extraction purposes." When cyanide was put on the free list by the Wilson tariff act in 1913, the output of the cyanide factory at Perth Amboy was not equal to the growing needs of the country, and it was necessary to import cyanide. At the outbreak of the war it was planned to operate on a larger scale and meet the increased demand. Mr. Ruhl gives the annual consumption of cyanide in the United States as 2000 tons, and of Mexico 5000 tons. According to figures of the United States Geological Survey given in our last issue, the domestic consumption is about 2500 tons per annum. Mr. Ruhl closed with the statement that "under the Dingley tariff of 12½ per cent *ad valorem*, an amount of protection with which we were quite satisfied, we were able at all times to supply the whole American demand. The raw materials we consume are sodium, ammonia and carbon."

Company Reports

Stratton's Independence, Ltd., has issued its annual report for the period ended June 30, 1914. The production of shipping ore, both on company and lessees' account continues to fall off as compared with previous years, and is expected to so continue. The mill treated during the year an average of 11,156 tons per month, the largest tonnage handled to date. The total working cost was $1.3811 per ton, the lowest to date. Deducting the cost of getting ore from the dump, the actual milling cost was $1.27 per ton. Extraction was a round 80 per cent, having increased 1.5 per cent over the previous year. The grade of mill ore fell from $3.076 in the previous fiscal year to $2.879 in the current year.

The mill handled 88,192 tons of dump ore and 45,683 tons of low-grade mine ore. The average gold content was 0.14396 oz. per ton, or a total of 19,273,469 oz. There was recovered in concentrates 7,654.77 oz., or 39.72 per cent; and in cyanide bullion 7764 oz., or 40.28 per cent; total, 80 per cent. The first-grade concentrate averaged 4.358 oz. gold per ton; second grade, 1.848 oz. These products were sold to smelters. The milling cost per ton was divided as follows:

Coarse crushing and sorting	$0.1563
Fine Crushing, concentrating and treating concentrate	0.5040
Cyaniding and special chemicals	0.1672
Miscellaneous expense	0.1425
Total milling cost	$1.2700
Mining dump ore	0.1100
Total cost	$1.3800

The gross profit from treating ore in the mill was $127,760, of which $26,251 was paid to the mine department on the usual schedule of treatment charges for milling low-grade mine ore, leaving a net profit to the mill of $98,509, on the treatment of 133,875 tons of ore.

The third quarterly report of the **Butte & Superior Copper Company** for 1914 shows 100,600 dry tons of ore milled. The average content was 18.58 per cent zinc and 8.64 oz. silver. The quantity of concentrate produced was 60,974,968 lb., containing 33,121,312 lb. metallic zinc, or 54.32 per cent. The average silver con-

tent of concentrate was 24.15 oz. per ton. Zinc recovery averaged 89.14 per cent. Milling cost $2.049 per ton. The estimated net profit for the quarter, calculated on spelter at 5.11 cents, was $499,136. The net spelter return per ton of ore, including estimated value of lead concentrates and zinc residues, was $10.21 as compared with $8.44 for the previous quarter.

The Non-Ferrous Metal Market

Since our last monthly report the prices for metals except tin have advanced, in some cases substantially. Following a brisk domestic demand for copper, European buying strengthened the market. Lead has remained at a low price, slightly in advance of a month ago. Spelter has advanced sharply, due principally to sales to Europe. Tin has declined, following a decline in London and lack of interest among consumers.

Copper.—Sales have been reported at 13 cents, and with renewed selling to Europe the market is firm. Most of the business, however, has been transacted at about 12.75 cents, New York.

Lead.—Business has continued light, but there is a sentiment that foreign countries may soon be in the market for this metal. New York quotations are about 3.80 cents, and St. Louis 3.67½ at 3.72½.

Tin.—This market has declined. Speculators on the London market raised the price for a time, but buyers were disinterested, and the market weakened. December tin in this market is about 32½ cents.

Spelter.—Early in December foreign orders for this metal caused prices to rise sharply. A large business has been done in exports and there is prospect of a continuance of a firm market. New York spelter is quoted at 5.65 cents, and St. Louis at 5.50.

Other Metals.—Business in aluminium has been slow and the volume of sales small. New York quotation is about 19 cents per pound for No. 1 ingots. Antimony prices are weaker in view of weaker demand, and various brands are quoted at from 13 to 16½ cents. The quicksilver market is quiet, with little change in prices. Flasks of 75 lb. are quoted at $52.50.

The Iron and Steel Market

The turn has occurred in the steel trade. The improvement in sentiment that became noticeable early in November has been followed in December by a buying movement which is by no means of spectacular proportions but which nevertheless represents a radical turn from conditions of recent months. In sheets and tin plates the actual shipping orders booked in December have been nearly double those of November. In bars, plates and shapes the increases have averaged 50 per cent or more, while in tubular goods and wire products there have been slight increases.

In most commodities the trend of prices is distinctly upwards. Throughout December the mills quoted 1.05c. on bars, plates and shapes for immediate specification and 1.10c. on contracts involving specification during the first quarter, and at the close of December there was a general withdrawal of the 1.05c. quotation. In wire products there are predictions of an early advance. In the sheet market prices have continued irregular, but have not declined further in the past week or two, and a stiffening in quotations is not improbable in the near future.

The Year's Results

The average level of prices in the finished steel trade in 1914 was the lowest for any year since 1898, when conditions were altogether different. In pig iron prices have averaged the lowest in recent years, but have not been as low as in 1904.

The production of pig iron in 1914 was about 23,200,000 gross tons, representing a decrease of 25 per cent. from 1913, the banner year. The decrease in steel ingots was greater and in finished steel products still greater, as some stocks of pig iron have been accumulated, and also at some plants there has been a little accumulation of ingots.

The smallness of profits in the year is illustrated by the fact that the United States Steel Corporation's earnings will fall between $70,000,000 and $80,000,000, the only year in its history showing earnings approximately as small being 1904, when the corporation's productive capacity was much smaller than at present.

Pig Iron

The pig iron buying in the Buffalo district late in November was followed by buying of importance in most other districts. The sales by Buffalo furnaces aggregated fully 200,000 tons, and the movement in the Pittsburgh district, somewhat later, involved about 125,000 tons. The Chicago district moved 100,000 tons or more. The movement in southern iron was not in keeping with that in northern, for instead of southern iron leading, as usual, the buying occurred later, and the volume was not large, perhaps 250,000 tons. While the pig iron buying movement as a whole did not by any means reach the proportions of some movements in the past, it represented the greatest concentrated activity for about a year. In some districts there was an apparent yielding in price, but this was simply the replacement of a nominal market by a real market. In the Pittsburgh district there was no change, while at Buffalo and Chicago there were advances after the iron had been sold. The market is now moderately active and prices are quotable as follows: No. 2 foundry, Birmingham, $9.50 to $9.75; delivered Philadelphia, $14.25; f.o.b. furnace, Buffalo, $13; f.o.b. furnace, Chicago, $13; at valley furnaces (95 cents higher delivered Pittsburgh): Bessemer, $13.75; basic, $12.50; No. 2 foundry and malleable, $12.75 to $13; gray forge, $12.50 to $12.75. Ferromanganese is nominally quoted at $68, Baltimore.

Steel

The market for billets and sheet bars is not closely quotable, as most transactions are really in the nature of price adjustments upon long term contracts. There have been offerings for prompt shipment at $18.50 for billets and $19 for sheet bars, at maker's mill, Youngstown, but for delivery over the quarter quotations are about 50c. a ton higher. The Pittsburgh producers are quoting about 50c. a ton higher at mill than the lowest Youngstown sellers.

Finished Steel

Prices quoted below are for contracts over two or three months. In some commodities lower prices for immediate shipment have been ruling, but these are largely withdrawn. Prices quoted are f.o.b. Pittsburgh, unless otherwise stated, but on many products the Chicago and eastern Pennsylvania mills are quoting lower delivered prices in their territories than the equivalent Pittsburgh prices plus freight.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.10c.

Shapes, 1.10c.

Steel bars and bands, 1.10c.; hoops, 1.25c.

Refined iron bars, 1.20c., Pittsburgh; common iron bars, 1.12½c., Philadelphia; .95c., Chicago.

Sheets, blue annealed, 10 gage, 1.30c.; black, 28 gage, 1.85c.; galvanized, 28 gage, 2.80c.; painted corrugated,

28 gage, 2.05c.; galvanized corrugated, 28 gage, 2.85c.

Tin plate, season price announced Dec. 3, $3.20 for 100-lb. cokes.

Steel pipe, ¾ to 3-in., 81 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 74 per cent off list.

Standard railroad spikes, 1.35c., Pittsburgh; 1.45c., Chicago.

Structural rivets, 1.35c.; boiler rivets, 1.45c.

Cold rolled shafting, 67 per cent off list.

Chain, ⅜ in. proof coil, 3.00c.

"The Little Journal" is the name of a new paper to be published "occasionally" by Arthur D. Little, Inc., chemists, engineers, managers, of Boston, Mass. The catchy name puts at once the reader into good humor, and creates high expectations. These are not disappointed. The contents are worthy of the name Little and what it stands for in American chemistry. There is no smack of amateurishness in this Vol. I, No. 1. Its editorial finish is really remarkable. An article on "raw materials and the war" sketches concisely how the supply of various metals, chemicals, drugs and dyes has been affected by the war. "Dyestuffs," "Radium in America," "Nitrocellulose in War and Peace" are the subjects of further articles, Ernest Solvay and Alfred Nobel the subjects of biographical notes. There are three brief editorials. In the first the cry for an immediate creation of an independent American dyestuff industry is amusingly ridiculed by the proposal to utilize American rainbows. The other two editorials refer to inevitable consequences of the war for the European nations. "European industry will be on a new basis when the war is over," because the overhead charges will be higher, "and costs of production will more nearly approach our own." As to the loss to science due to the war, "the loss to science and the world would have been no less disastrous though unappreciated had Faraday and Curie and Solvay and Helmholtz and Mendeleef fallen on the firing line at twenty-one." We extend to "The Little Journal" our cordial wishes for a long and glorious career.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in September, 1914, was 60. The total quantity of ore milled during that period was 2,242,913 tons. There were 9795 stamps in operation with an average duty of 8.86 tons per 24 hours. Tube mills in commission numbered 292. The yield for the month was 702,170 fine ounces gold.

Bolivian mineral exports, according to American Minister John D. O'Rear, at La Paz, are mainly in the form of high-grade concentrates. There are no smelters in the country. The following table shows in kilos (1 kilo = 2.2046 lb.) the exports of the principal minerals for the last few years:

Minerals	1908 Kilos.	1909 Kilos.
Tin	29,938,282	35,566,415
Silver	156,482	155,360
Copper	2,877,605	3,096,605
Bismuth	160,304	236,762
Wolfram	169,637	152,600
Zinc	1,242	602,000
Lead	5,150	7,000
Antimony	919,735	494,440
Gold	35	42
Total	34,228,472	40,311,224

Exports for the first eight months of 1914, reported in kilos, were: Tin, 26,021,564; silver, 12,624,754; copper, 202,265; bismuth, 163,520; wolfram, 145,780; antimony, 120,770.

"Ironised" Steel Tubes.—From a note in the London *Electrician* of November 20, 1914, we learn that noncorrosive steel tubes will soon be on the market, as the British Mannesmann Tube Co. (Ltd.) have just completed a plant for ferro-zincing and ironizing tubes, under license from Mr. S. Cowper-Coles. "It is a well-known fact that the purer the iron the less liable it is to pitting and corrosion, chemically pure iron being practically rustless. 'Ferro-zincing' or 'ironizing' turns these facts to account by coating the steel surface with almost pure iron, the only impurity of any significance being hydrogen. The addition of hydrogen is an advantage, for the reason that it makes the iron slightly more electropositive to the underlying steel than it would otherwise be, so that it forms a better protective coating. Another advantage of the coating of electrolytic iron is that the coating is homogeneous, and is not under unequal strain caused by mechanical operations, such as drawing or hammering, and has not been subjected to any heat or mechanical treatment which, of necessity, caused impurities to be absorbed by the metal so treated. It is advantageous for many purposes to coat the electrolytic iron surface with zinc, as a zinc coating with an intermediate layer of pure iron-hydrogen alloy gives a greatly increased life to an ordinary steel tube or plate."

Operating Data on Copper Smelting Furnaces.—The following data, taken from "The Copper Smelting Industries of Canada," a bulletin issued by the Canadian Department of Mines, gives the principal data regarding the operation of the furnaces of the British Columbia Copper Co., Greenwood, B. C. There are three water-jacketed blast furnaces. Originally these furnaces were 48 in. by 240 in. at the tuyeres; the capacity was recently increased about one-third by widening the two end furnaces to 51 in. and lengthening them to 360 in.

Charge, tons per sq. ft. hearth area, 24 hr.	6.2
Per cent copper on charge	0.8-1.2
Per cent sulphur on charge	1.6-3.5
Per cent sulphur burnt off	80.0
Per cent coke on charge	12-14
Per cent ash in coke	22-25
Blast, cu. ft. per min.	25,000
Blast temperature	Atmospheric
Cooling water for jackets, gal. per hr. 3 furnaces	4,000
Men in 8-hr. shift	20
Matte, per cent of charge	2.0
Matte, per cent of copper	40.0
Matte, sp. gr.	5
Slag, per cent SiO_2	43 -46
Slag, per cent Fe(Mn)O	19 -27
Slag, per cent Ca(Mg)O	21 -28
Slag, per cent Al_2O_3	6 - 9
Slag, per cent Cu	0.2- 0.25
Slag, per cent sp. gr.	3.2

The Nipissing Company, of Cobalt, Canada, has been making no shipments of silver bullion for several weeks. As a consequence the silver shipments from Cobalt have been below the normal. On the 10th of November the shipments from the O'Brien and Dominion Reduction were valued at $48,243.

Nevada's mineral production for 1913 has been valued by the U. S. Geological Survey at $37,842,084, as against $39,111,828 in 1912.

1910 Kilos.	1911 Kilos.	1912 Kilos.	1913 Kilos.
38,548,441	37,073,148	38,614,228	44,594,749
142,977	127,990	123,939	81,289
3,211,987	2,950,023	4,707,188	4,019,635
311,060	414,598	477,748	422,664
210,061	297,272	474,640	282,577
11,897,000	9,795,125	8,961,352	7,367,463
30,485	313,188	1,071,887	1,763,206
524,878	311,715	91,350	.....
.....	55	78	93
54,876,889	51,316,114	54,525,410	58,531,676

The Boss mine, in the Yellow Pine mining district, Clark county, Nevada, in which platinum has been found, is reported to have been sold for $250,000. Another discovery of platinum ore in the same district is reported from the Aura Amigo mine.

The nitrate industry of Chile is reported seriously affected by world conditions. Small towns have become almost depopulated, commerce is at a stand-

still and financial conditions are unfavorable. The Chilean government has advanced about $1,396,000 to companies that have applied for assistance. Consul D. J. D. Myers of Iquique, Chile, believes, however, that American manufacturers can secure business when normal conditions are resumed.

The Aurora mill in Nevada has adopted trays in Dorr thickeners to increase settling capacity.

The new mill of the Alaska Gold Mines Co. will present a new departure in gold milling. The ore will be coarsely broken with jaw crushers and gyratories, followed by two series of rolls. This will reduce the ore to a degree of fineness appropriate for rough concentration. The next step will be grinding in pebble mills, followed by the usual methods of concentration and amalgamation. The most radical departure from customary practice is in the abandonment of stamps and the adoption of methods heretofore applied to the porphyry copper ores.

Copper Blast Furnaces and Converters in Canada

There are 29 rectangular water-jacketed copper blast furnaces in Canada at the present time, the majority of which have been in active operation up to the opening of the European war. The total hearth area of these furnaces is 2,580 sq. ft. and the total rated capacity is 15,600 tons in 24 hours. The actual duty varies considerably at the different plants, on account of the differences in ore treated. The following table, taken from Bulletin 209 of the Canadian Department of Mines, prepared by Alfred W. G. Wilson, gives the principal data:

Company	No. of furnaces	Tuyere dimensions	Hearth area in sq. ft.	Ore column, ft.	Approx. rated capacity, short tons
Canadian Copper Co.	5	50x204	70.83	14	400
	1	50x240	83.33	14	550
Mond Nickel Co.	2	50x240	83.33	12	550
Cons. Min. & Smelt. Co.	1	42x210	61.25	8	350
	1	42x360	105.00	8	650
	1	42x264	77.00	8	460
	1	42x420	122.50	8	700
	1	50x420	145.80	8	875
Granby Cons. Mining & Smelting Co. Grand Forks	6	44x266.5	81.41	12	500
	2	48x260	86.67	12	550
Anyox	3	50x360	125.00	12	750
B. C. Copper Co.	2	51x360	127.50	12	800
	1	51x240	85.00	12	500
Tyee Copper Co.	1	42x120	35.00	6	200
	1	48x160	53.33	6	300

Five out of the seven copper smelting plants in Canada are equipped with converters. The following tabulation gives the principal data:

Company	Type	Stands	Shells	Dimensions
Canadian Copper Co.	Basic. Pierce - Smith Special	5	5	10′ 0″x37′ 2″
Mond Nickel Co.	Basic. Pierce - Smith Standard	2	2	10′ 0″x25′ 10″
Granby Cons. M. & S. Co.: Grand Forks	Basic. Power & Mining Mchy Co. Acid shells	3	10	84″x126″
Anyox	Basic. Great Falls type	3	3	12′ 0″x5′ 9″
B. C. Copper Co.	Acid. Allis-Chalmers	2	5	84″x126″

The Dome Mines Co., Porcupine, Canada, milled the largest tonnage in its history during October, treating 22,500 tons of $4.70 ore.

Ray Consolidated Copper Co. has advised stockholders that the directors have deemed it wise to defer payment of the quarterly dividend which would have been declared payable on December 31, 1914.

A tin concentrating mill recently erected at the Leeuwpoort mine in the Transvaal, is said by the *South African Mining Journal* to represent "the last word in tin mining equipment in this country," if not in the world. The plant contains Californian and Nissen stamps, Harz jigs, Richards-Janney classifiers, Buss and Wilfley tables, Isbell vanners and Dorr thickeners—a line of concentrating machinery that will have quite a familiar sound to every American millman.

Gold deposits in the assay office of the United States at Seattle, Wash., during the fiscal year ended June 30, 1913, as reported by the Director of the Mint, amounted to 239,557,528 fine ounces, valued at $5,006,750.25. Of this amount Alaska contributed 173,228,343 fine ounces. The total deposits in this office since its establishment July 15, 1898, to the close of business June 30, 1913, amounted to 12,294,-202.83 fine ounces gold, having a coining value of $211,363,034.76, of which Alaska contributed $106,-248,265.09.

Platinum, palladium and osmiridium are recovered as by-products of refineries in the United States Mints. The following table shows these recoveries for the fiscal year ended June 30, 1913:

	Sponge platinum		Sponge palladium		Osmiridium	
San Francisco	205.74	$895.99	...	.....	0.35	$1,400
Denver	58.20	2,328.00	10.15	$406.00	...	.....
New York	1,403.00	59,712.09	18.10	760.20	...	.....
	1,666.94	$62,936.08	28.25	$1,166.20	0.35	$1,400

Mill Tailings for Road Metal.—In Missouri a considerable amount of road material is obtained from the tailings of the concentrating mills at the zinc mines. This material, which is put on the market as "chats," consists of small angular fragments of chert and limestone. The zinc companies are very glad to get rid of this waste material, which is loaded on the cars by the railroads of the district at a cost of about 6 or 8 cents a ton. It makes more than ordinarily good roads and is widely distributed all through the Middle West. It sells in most places at prices ranging from 50 cents to $1 a ton, but in the neighborhood of the mines it can be had for about 15 cents a ton. It is used for railroad ballast as well as road making. The annual output, according to the United States Geological Survey, amounts to not less than 1,300,000 tons.

The Nevada Cinnabar Co., operating at Ione, Nevada, is reported to have shipped several carloads of flasks of quicksilver to the New York market. The furnace is producing from 20 to 25 flasks of metal daily.

Labor Conditions at Butte.—Labor disturbances at Butte have assumed a new phase: dissension exists within the labor unions, and not between companies and unions. Butte is a copper mining district, and as copper production is affected by the European war, the possibilities of a labor shortage at this time have no terror for the companies. In fact they have taken a radical step in declaring for the open shop in Butte, and hereafter the possession of a union card will not be a prerequisite for holding a job, nor will union representatives be permitted to visit the mines to inspect such cards. Butte has long been a stronghold of unionism and the companies have always dealt with unions, but contending union factions have brought about their own downfall.

Ignition of Gas by Fracture of Small Lamp Bulbs.—In a paper read by Mr. E. A. Hailwood at a recent meeting of the Midland Institute of Mining, Civil and Mechanical Engineers, at Leeds, the author declared that the commonly accepted opinion that it was not possible to ignite gas by the breaking of a small electric lamp bulb was entirely erroneous, and that he had in his experiments produced hundreds of ignitions by that means. He thought that such ignition might possibly be explained by the gas which rushed in to fill the destroyed vacuum being momentarily compressed against the red-hot filament with consequent explosion. He doubted whether the insertion of a fuse would be a remedy. The lamps in question were about 1 to 1½ cp.

An Electric Muffle Furnace for the Determination of Carbon and Oxygen in Steel and Tungsten Powder

BY CHARLES MORRIS JOHNSON

In 1908, the writer introduced the determination of carbon in iron, steel, etc., by means of the direct ignition with oxygen in an electrically heated furnace. (*Journal*, Am. Chem. Soc., Vol. XXX, No. 5.) Several months ago, he designed a muffle furnace for this purpose which has so many advantages over the original model that he is replacing the twelve furnaces of the old form with this new muffle type in the Park Works laboratory of the Crucible Steel Company of America.

The illustration shows the simplicity of construction. The furnace in the foreground of the picture and containing the tapered clay combustion tube (see Analysis of Special Steels, page 244, for a description of this tube) consists of a split cylindrical muffle of special non-heat conducting composition, of a hoop iron frame, and the nichrome heating element embedded in refractory cement. This heating element is to be seen in the cut, lying on the table in a half muffle. The wire is *not* wrapped around an inner core tube but is covered with the cement and dried on a form. Drying on a form was originated by Mr. I. A. Nicholas for such work.

The four furnaces connected in trains of apparatus show the modification that the author uses for the determination of oxygen. If it is desired to cool these furnaces rapidly, the current is shut off and the top half of the muffle is removed. Those desiring further details of the oxygen method should consult pages 74 to 82 of "Special Steels."

ELECTRIC MUFFLE FURNACE FOR STEEL LABORATORY

The advantages of this muffle furnace construction are: Very low first cost, ease of repair, quick heating and quick cooling. The furnace on a 220-volt direct current will heat from the cold to 1000 deg. C. in from fifteen to twenty minutes! It also presents a cleaner and much brighter appearance than the older style which has a case of black iron. It is easily kept clean and cheerful looking by an occasional dusting, together with the application of some fine-grained sandpaper.

Being of acid-proof material, the muffle is, of course, unaffected by fumes. There are no screws or insulating powder to bother with when the heating element has to be renewed. The later merely is slipped into place.

The following figures give an idea of how cheaply one can build such a furnace:

One split muffle	$2.00
One hoop-iron frame	2.00
Flexible cord and connections	1.50
Heating element	4.50

If the heating element is prepared in the laboratory and the frame support is made by the smith in the works, the above cost can be reduced several dollars.

Pittsburgh, Pa.

Apparatus for the Concentration of Sulphuric Acid

BY WILLIAM MASON

The concentration of sulphuric acid simply means the separation of the acid from water by the process of evaporation. The sulphuric acid as it issues from the chamber system is usually of a specific gravity of 1.560, containing 65.27 per cent of sulphuric acid, and is evaporated until it attains the specific gravity of 1.840 or contains about 96 per cent of sulphuric acid. The weak acid begins to lose water at about 122 deg. Fahr. and boils at 305 deg. Fahr. The strong acid boils at 563 deg. Fahr.; but it is known that this sulphuric acid may be concentrated at a temperature much below its boiling point, namely, at a temperature of about 450 deg. Fahr.

The construction of apparatus for the concentration of sulphuric acid has, at times, had considerable attention. Many forms of apparatus have been invented, and many metals have been used in their construction from brittle glass to the expensive metals of gold and platinum. Of late years apparatus have been built of volcanic lava, but these, it will easily be seen, are very expensive, costing as much at £1,500 ($7,500). It is a fact that although some of these apparatus produced acid much cheaper, requiring less fuel and reducing the cost of labor, they very rarely produced it equal in color to that which was produced by the old-fashioned glass retorts; and, for this reason, the glass retorts are found working in some works to-day.

In the year 1890, Negrier introduced what is known as the capsule system of construction which was further improved upon by Benker. It is an attempt to evaporate fractionally. This form of apparatus has had a very varied career. In the first plant porcelain capsules were used, and it may be that, from the fragile nature of this material, it was not persevered with. However, with the invention of a fused silica material for this purpose, this form of apparatus has again appeared, and plants of the capsule type have been erected in many places, again with varied results. Some

firms, after several trials and experiments with furnaces of varied construction have discarded them, preferring the type of apparatus in which the sulphuric acid is concentrated by contact with the furnace gases; but this type of apparatus does not produce an acid as clear as that which is made by the capsule or glass retort systems.

The author, having had several years' practical experience with a capsule plant, gives in the accompanying drawing a description of a plant which gives most satisfactory results. Fig. 1 is a plan, Fig. 2 is a sectional elevation, Fig. 3 a section through *EF*, Fig. 4 a section through *LM*, Fig. 5 a section through *GH*, Fig. 6 a section through *JK*.

Table I (p. 17) is also a specification of the cost of a plant to produce 4 tons of sulphuric acid in twenty-four hours.

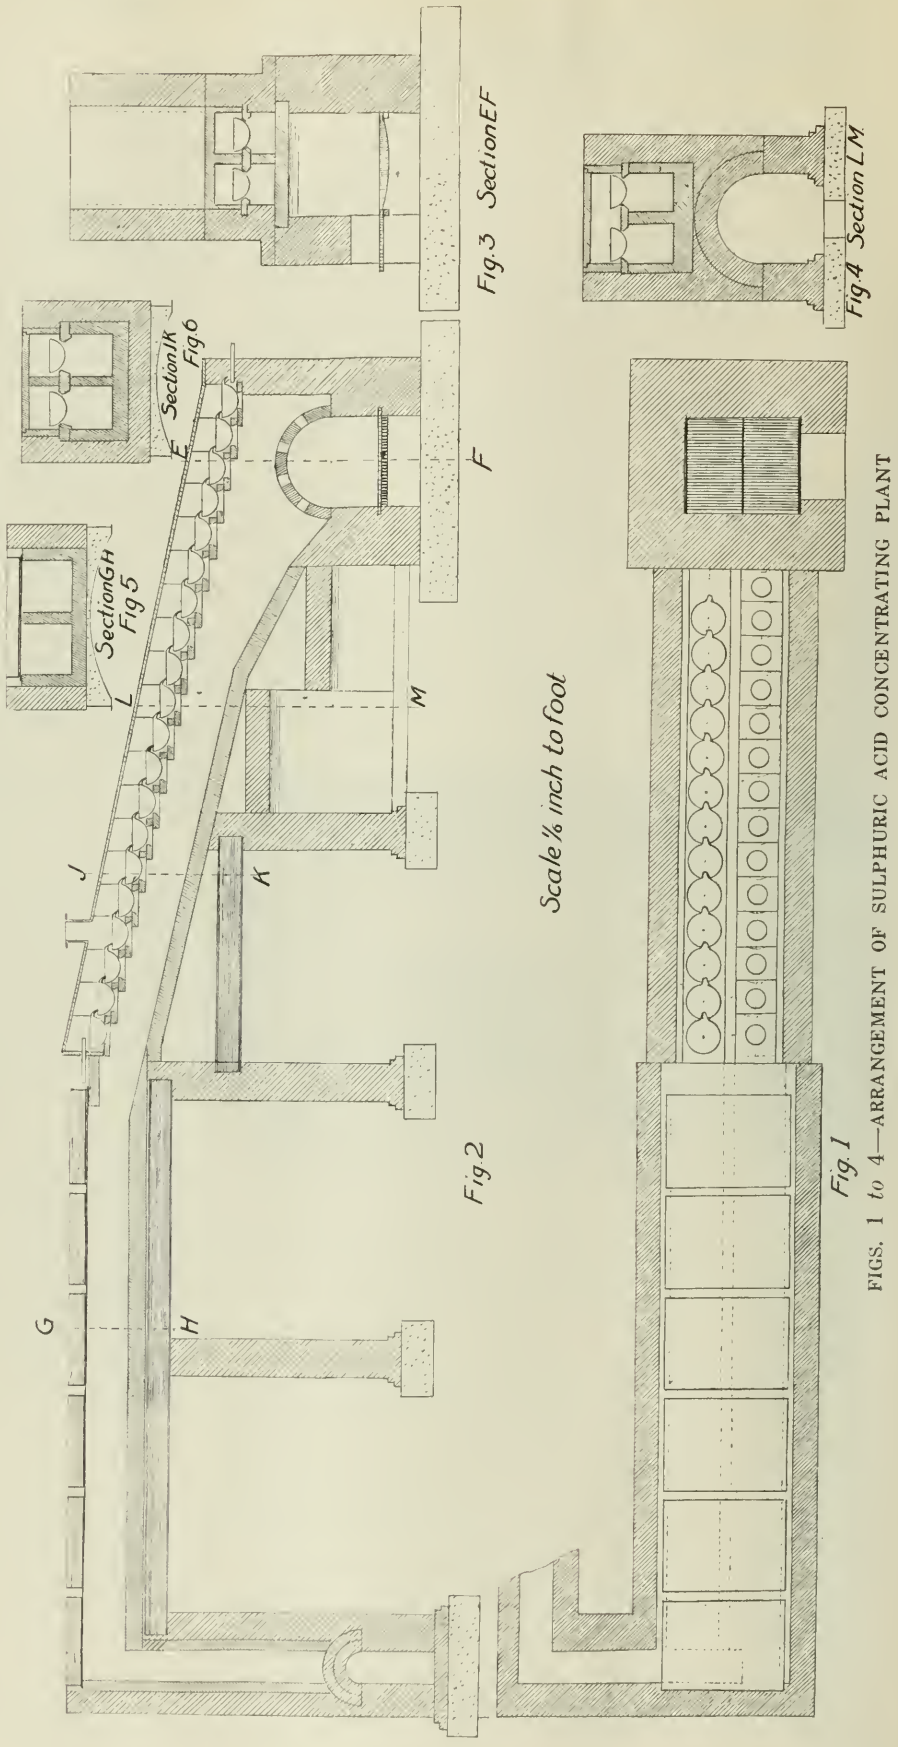
The cost of producing 1 ton of sulphuric acid by this plant was as given in Table II.

The working of this plant shows that the concentration of the sulphuric acid proceeds as stated in Table III.

The weak acid recovered by condensing the exit-gases was of a specific gravity 1.240 and was equal to 2.23 per cent of the weight of the acid produced. In the glass retort system the acid in the weak acid was usually equal to about 15.0 per cent of the acid produced.

The great drawback in constructing this type of apparatus has been that of using a forced-draught furnace. Such a furnace gives too high a temperature in the lower part of the plant, which causes much bumping of the capsules. In this way most of the capsules have been broken. An ordinary furnace with careful and regular working of same will produce economically a very colorless acid of satisfactory strength.

Oxford, England.



FIGS. 1 to 4—ARRANGEMENT OF SULPHURIC ACID CONCENTRATING PLANT

Quicksilver producers in the United States now have an opportunity to capture the trade with Central and South America and with the Orient from Japan to India, according to a statement by the U. S. Geological Survey. Austrian production, controlled by the government, is cut off from the world market; Italian supplies are considered uncertain; and the Spanish output is controlled in London and probably is not available for foreign trade. Domestic prices for quicksilver had been ranging from $39 to $37.50 per flask of 75 lb. until the war broke out, when they rose rapidly to from $75 to $90 per flask. The price has since receded to about $55. The Nevada Cinnabar Co., operating at Ione, Nev., is reported to have recently commenced production at the rate of sixty flasks per week.

Refractometry

BY G. A. SHOOK.

III.—Measurement of Refractive Index and Dispersion

As was pointed out in the first article of this series, it is more logical always to express the refraction of any substance in terms of the refractive index for sodium light than in terms of the scale divisions of some particular instrument.

Nevertheless it is manifestly more convenient in certain classes of analysis to express the refraction in terms of an arbitrary number. For example, it is somewhat simpler to designate the refraction of olive oil as 60.2 scale divisions (Butyro Refractometer) rather than in terms of the index for sodium light, namely 1.4660 and since adequate tables are accessible for converting the scale divisions of any arbitrarily graduated instrument into refractive indices—an arbitrary scale is really not objectionable.

Again in the case of an instrument like the Pulfrich refractometer which reads in circular degrees it is necessary to use a table and if the latter is properly constructed the index can very easily be obtained. Other things being equal it is, to be sure, advantageous to have the instrument graduated in refractive indices, but it is not always advantageous to sacrifice accuracy for convenience. On the Zeiss immersion refractometer scale, for example, one scale division corresponds to an increment in the index of about 0.0004 and by means of a vernier a tenth of a scale division can be accurately read, but in the Abbé instrument the fourth decimal place must be estimated. Therefore while the Abbé instrument gives the index directly and while its range is much greater than that of the Zeiss, it is not nearly so accurate.

The Féry instrument, however, has a wide range, but at the same time possesses an accuracy somewhat greater than that of the Abbé.

In the case of a comparatively simple instrument like the Butyro-refractometer, no special directions need be given for its manipulation but with a more complicated instrument like the Pulfrich refractometer it is quite different.

The method of manipulating two of the more complete instruments will now be considered in detail.

Manipulation of the Pulfrich Refractometer

This instrument is used primarily for research work, but it could undoubtedly be adapted for many kinds of commercial analysis.

As a research instrument it possesses many advantages over all the other types of refractometers. It is usually provided with two or three prisms of different refractive powers so that it may be used for practically all ranges. One is also able to measure, not only the index for sodium light but also the index for the *C*, *F*, and *G'* lines. Moreover the mean dispersion $n_F - n_C$, and the partial dispersions $n_D - n_C$, $n_F - n_D$, etc., may be determined. Finally an accuracy is here attainable which is greater than that of any other instrument of its range with the possible exception of the Féry refractometer.

For commercial work it has first of all the advantage of accuracy. Moreover, it is provided with a double cell so that the index of any liquid, say cottonseed oil, may be determined by comparing it with a standard oil. It is only necessary in this case to measure the difference between the two indices, and such a measurement can be made with greater precision than is possible in the measurement of the index. Moreover, since the variation of temperature will be practically the same for the standard and for the unknown oil, the measurement may be made at any temperature whatever.

The oléoréfractomètre of Amagat and Jean utilizes the same principle. This is an excellent instrument, but it is practically unknown in this country.

On the other hand, it is not quite so easy to make a rapid examination of a large number of samples with the Pulfrich instrument as with the Butyro refractometer or Abbé refractometer, for it is more difficult to clean the cell of the Pulfrich refractometer than the face of either the Abbé or the Butyro refractometer double prism. Again, the measurement of the index for the *C*, *F* and *G'* line is carried out by means of a hydrogen tube which is actuated by a small induction coil, and the latter is always a source of trouble.

For industrial use the hydrogen tube should be replaced by a commercial mercury lamp or some similar sort of monochromatic illuminator that can be run on any 110-volt alternating-current circuit.

For a red line a salt of lithium might be volatilized in the flame of a Merker burner just as we produce sodium light from fused sodium chloride. For a green line a thallium salt might be used. The tables furnished with the instrument would not, of course, be applicable if other lines than the *C*, *F* and *G'* were utilized.

There are numerous devices for controlling the temperature of the refractometer prism, but the one now generally sent out with this instrument is perhaps the most satisfactory.

Since the index of an oil is decreased by 0.000365 for each degree rise of temperature, it is essential to maintain the temperature of the cell within a few tenths of a degree.

Adjustment of the Pulfrich Refractometer

To adjust the hydrogen tube, *H* Fig. 1, fill the cell *C*

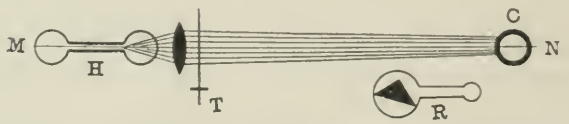


FIG. 1—DIAGRAMMATIC VIEW OF THE PULFRICH REFRACTOMETER

with any liquid (water will do) and turn the reflecting prism *R* out of the path of the rays from the tube *H*. By reference to the tables, furnished with the apparatus, for the particular prism, estimate roughly the position of the *C* line and then turn the telescope to this position so that when the cell is properly illuminated the *C* line will appear in the field of view.

With the current passing through the tube adjust the latter so as to produce the best illumination. Considerable care may be required to make this adjustment, for if the axis of the capillary tube is not in line with the optical axis of the instrument *M N*, the brightness of the lines is seriously impaired.

The cross wires in the telescope are always set on the upper edge of the line and not on the lower. By means of a shutter *T* the light coming from the upper half of the collimating lens may be cut off. By cutting out all of the extraneous light with this shutter the lines are rendered more distinct. If the entire aperture of the lens is exposed, they become ill-defined and an accurate setting is made impossible.

The *C* line is bright red and with most liquids sharp on the upper edge. The *F* line is blue-green and it is difficult to distinguish it from the other green lines that lie between it and the *C* line. The *G'* line is very faint and difficult to work with. Even the *F* line cannot be seen in the case of a liquid like butter.

If the tube happens to contain impurities such as mercury, water vapor, etc., other lines will be present

which may obscure the *C*, *F* and *G'* lines or at least confuse the observer as to which is the *F* or *G'* line, as the case may be.

The quickest way of identifying the *F* line is to take the index of water for the *F* line, which at room temperature is about 1.338, and determine from the tables the angle at which the telescope should be set so that the cross wires will be just about on this line. By turning the telescope to this position the line may be easily identified.

Before making any measurements it is necessary to make certain that when the telescope is in the position to receive the rays leaving the refractometer prism normally the reading on the circular scale is zero. This normal position is determined by means of an eye-piece of special construction.

A portion of the cross wires *W*, Fig. 2, in the focal plane of the telescope, is intercepted by a reflecting

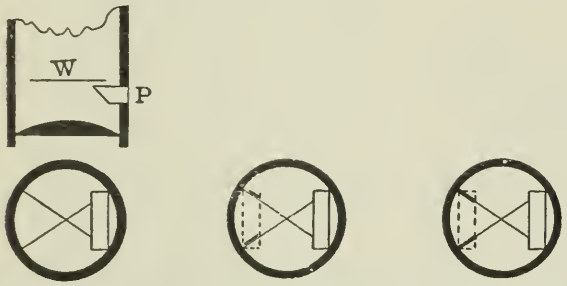

FIG. 2—CROSS WIRES OF THE PULFRICH REFRACTOMETER TELESCOPE

prism *P*. If light is admitted to this prism by placing the apparatus near a well-lighted window or by simply holding a light near the eye-piece (to the right of the observer), an image of that part of the cross wires which is cut out by the prism *P* will be formed on the opposite side of the field of view as shown by the second diagram.

This image is due to the light which is transmitted down the telescope and reflected back again by the vertical face of the refractometer prism. Consequently, if the incident beam strikes the prism surface normally it will be reflected normally, and therefore the image of the wires will coincide with the wires themselves as shown in the third diagram of Fig. 2.

The telescope should be rotated until this condition of coincidence obtains and then the reading of the circle should be noted. If it does not read zero, a correction should thereafter be applied.

The support carrying the prism and cell should always be clamped to the standard to which it belongs before making any measurements.

The circle *A*, Fig. 3, of the instrument reads to min-

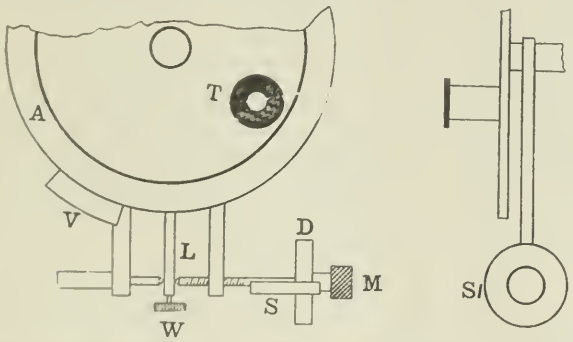

FIG. 3—MICROMETER OF THE PULFRICH REFRACTOMETER

utes by means of a verner *V*, but if a fraction of a minute is desired the micrometer *M* is used.

When the screw *W* is tightened, the circle is clamped rigidly to the lever *L*, and it can then only be rotated by means of the micrometer *M*. By means of *M* the circle, and consequently the telescope, may be turned through six degrees. The drum *D* is divided into 20 parts and each part represents one minute. The tenth part of a minute can be read directly from the drum and this is as close as one can set the cross wires under the most favorable circumstances.

This range of six degrees is long enough to measure the dispersion of any substance so that the circle need not be read for dispersion measurements after it is once adjusted and clamped by the screw *W*.

In the tables furnished with the instrument the index for the *D* line is given for every ten minutes, and the value for each minute must be determined by interpolation. For each of the ten minutes of angle a "correction," so called, is given to be applied to the *C*, *F* and *G'* lines. The method of obtaining data for the determination of the index for any line may be best illustrated by means of an example.

With water in the cell the angle for the *D* line, as read from the circle, was 67° 28′ and the micrometer read 2° 40′. For the *C* line the micrometer read 1° 49′, and for the *F* line 5° 13′. The angular difference for the *D* and *C* lines is therefore

$$2^\circ\ 40' - 1^\circ\ 49' = 51'$$

and consequently the angle corresponding to the *C* line is

$$67^\circ\ 28' - 51' = 66^\circ\ 37'.$$

In like manner the angular difference for the *F* and *D* lines is

$$5^\circ\ 13' - 2^\circ\ 40' = 2^\circ\ 33'$$

and the angle for the *F* line is

$$67^\circ\ 28' + 2^\circ\ 33' = 70^\circ\ 01'.$$

From the table, for the particular prism, the index for the *D* line corresponding to an angle of insidence equal to 67° 28′ is 1.33328.

For the angle 66° 37′ the index of refraction for the *D* line is, from the table, 1.33728, and the correction for the *C* line is — 596, whence the index for the *C* line is

$$1.33728 - 596 = 1.33132.$$

The n_d corresponding to the angle 70° 1′ is 1.32196 and the correction for the *F* line is + 1517, whence the index for the *F* line is 1.33713.

We finally have the following results:

$$n_c = 1.33132$$
$$n_d = 1.33328$$
$$n_f = 1.33713$$

and the mean dispersion is

$$n_f - n_c = 0.00581$$

Manifestly this computation is far too laborious to render the method applicable industrially. If a large number of observations are to be made it is decidedly advantageous to make out a table giving the index corresponding to the *C*, *D* and *F* lines for each degree. This table need include only values for the particular range in which the experimenter is working.

The writer, for example, made out such a table extending from 42° to 48°, and this range corresponds to a range of refractive indices from $n_d = 1.4417$ to $n_d = 1.4775$ for prism *I*b. This table is suitable for most of the edible oils. A portion of it is given in Table I.

TABLE 1—REFRACTIVE INDICES FOR PRISM Ib

Angle	D	C	F
42° 0′	1.4775	1.4721	1.4911
1	74	20	10
2	73	19	09
3	72	18	08
4	71	17	07
5	70	16	06
47° 57′	1.4420	1.4365	1.4559
58	19	64	58
59	18	63	57
60	17	62	56

Furthermore, since it is easier to read the micrometer than the vernier, of the circle, the former should always be used and it should be set so that some number on the micrometer corresponds to a particular number on the circle. The necessity for making a subtraction each time is thus obviated.

For the above table the circle was set at 45° and held there firmly. The screw *W* was then released and the micrometer was set at 2°. It is easy enough to remember that 2° on the micrometer scale *S* corresponds to 45° on the circle and that 1° corresponds to 44°, etc.

The angle can thus be easily read to one-tenth of a minute, if justifiable, and by means of such a table as is shown above the index for either the *D*, *C* or *F* line may be found directly.

While the index for sodium changes markedly with the temperature, the mean dispersion $n_F - n_C$ changes only slightly, indeed less than one part in the fourth decimal place for a temperature change of about 10° C. Therefore if the mean dispersion were measured at room temperatures a few degrees of fluctuation of the temperature would not affect its value and therefore the temperature would not have to be taken into account.

For some classes of work this constant might be as useful as the index for sodium light. The mean dispersions for a few oils are given in Table II.

TABLE II—MEAN DISPERSION OF EDIBLE OILS (45° C)

Oil	n_d	$n_f - n_c$
Cedar	1.50570	0.01031
Linseed	1.45928	0.01018
Castor	1.47027	0.00904
Cod liver	1.46984	0.00988
Lavender	1.46084	0.00953
Cottonseed	1.46394	0.00953
Hempseed	1.46889	0.00962
Rapeseed	1.46553	0.00933
Sesame	1.46429	0.00932
Olive	1.46040	0.00877
Butter	1.45296	0.00784
"	1.45246	0.00839
"	1.45226	0.00828
Cocoanut	1.44746	0.00739
Margarine	1.44606	0.00832

These values are taken from the recent work of Szalágyi.

The values of the mean dispersion for all liquids of commercial interest have never as yet been accurately determined and therefore can not be given.

With dark colored solutions it is difficult to make an accurate setting on the *F* (green-blue) line and therefore the mean dispersion in such cases can not be accurately determined unless a stronger light than that emitted by a hydrogen tube is available. With a high-power mercury lamp such a measurement could be easily carried out.

With transparent solutions, however, the mean dispersion can be determined to an accuracy of about two parts in the fifth decimal place.

Failure of the Refractometer to Detect Adulterants

While the refractometer may be successfully used to indicate the purity or the uniformity of a simple product like olive oil or natural butter, it may be easily demonstrated that it is practically useless for detecting the presence of a number of adulterants.

One often finds in reliable books on food analysis a statement to the effect that if the index of refraction (for some standard temperature) of a certain product, say, butter, does not exceed a particular value, the sample may be pronounced pure and chemical analysis may be dispensed with. Let us consider the following cases:

The limits of the index of refraction for natural butter at 25° C., according to Wollny, are 1.4590 to 1.4620. For most oils the index decreases by about 0.00037 for each degree rise in temperature so that for 35° C. the corresponding limits are approximately 1.4553 to 1.4583. Woolny suggests that, to remove all chances of adulterated butter escaping detection, the upper limit should be still lower at 35° C., about 1.4573.

A given sample of creamery butter examined by the writer gave an angular reading of 45° 35′ and the index for this angle, from his table, was found to be 1.4562, which is clearly within the limits of pure butter.

A sample of oleomargarine gave a reading of 1.4590, which is a little low, but not low enough, of course, to pass for butter.

For a cocoanut oil a value of 1.4498 was found for the index.

A mixture consisting of 2 cc. of oleomargarine and 1 cc. of cocoanut oil, upon examination gave a value of 1.4560 for the index, which is also within the limits of pure butter. Moreover, this mixture since its refraction is practically identical with the refraction of pure butter, could be used to adulterate butter to any degree whatever.

A second mixture consisting of 1 cc. of the first mixture (oleomargarine and cocoanut oil) and 1 cc. of butter gave for n_D a value of 1.4562. To be sure, there are other methods for determining the adulterants of butter, but it is evident from these examples that mixtures can be compounded which will render the refractometer useless.

Again, if the butter were low, a considerable amount of oleomargarine could be added before it reached the upper limit or if its index were high it might be adulterated with cocoanut oil.

Consider another example: A sample of olive oil gave a value of 1.4628 for n_d. At a temperature of 25° C. the limits for olive oil are 1.4660 to 1.4680 and for 35° C. about 1.4623 to 1.4643, so that this oil was within the limits, but had a rather low index. It was adulterated by adding an equal volume of cottonseed oil with the result that the index was increased to 1.4638, which is still within the limits.

The mean dispersion for this mixture was found to be 0.0090, but this difference in disperson is hardly great enough to pronounce the sample impure. If we had instruments for detecting smaller differences in the mean dispersions we might make use of this constant for detecting adulterants. However, it would not be difficult to produce a mixture which would not only possess the desired index but also at the same time any desired mean dispersion.

A second mixture consisting of 2 cc. of cottonseed oil and 1 cc. of cocoanut oil give for n_d a value of 1.4612 which is just below the lower limit. A smaller amount of cocoanut oil would bring the mixture within the limit. The mean dispersion in this case was 0.0086.

For a mixture of 2 cc. of lard oil and 1 cc. of cottonseed oil the index was found to be 1.4638. Varying amounts of this mixture could, of course, be added to olive oil as desired.

It is thus seen from the above examples that while an abnormally high or low refraction may be a sufficient characteristic of an adulterated product, it is most certainly not a necessary characteristic.

As far as the refractometer alone is concerned the unscrupulous manufacturer may easily deceive the analyst.

This is, however, only one of the many uses for the refractometer so that its value in chemical analysis must not be depreciated.

Manipulation of the Abbé Refractometer

The initial adjustment of the Abbé refractometer is now usually made in the following manner:

The telescope is rotated about the horizontal axis of the instrument until the plane of the upper prism is nearly horizontal, as shown in Fig. 4. A rectangular glass plate optically plane on one face and one end is

furnished with the instrument and its index for sodium light is 1.5176. A drop of monobromonaphthalene (n_d = 1.658) is placed on the prism face and the test plate is then placed on the prism. If the plate is held in place in any manner the instrument need not be rotated into this rather awkward position for making an observation.

It is necessary that the liquid between the two surfaces have a greater index of refraction than the plate, but the value of the index of the liquid is not used in any computation. The prism, by means of the alidade, many now be slightly rotated until the intersection of the cross wires coincides with the boundary or critical line. If the critical line is not colorless rotate the compensator until all color disappears. If the instrument now reads 1.5176 no further adjustment is necessary and it will read correctly throughout its entire scale.

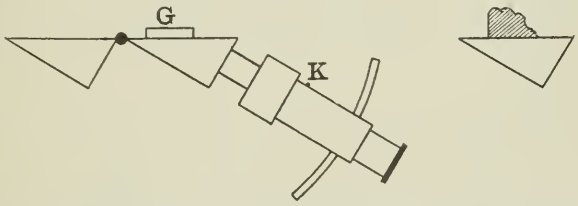

FIG. 4—EXAMINATION OF SOLIDS BY ABBE REFRACTOMETER

If, however, it does not indicate this value it can be made to do so by slightly shifting the cross wires. This is done by inserting a watch-key at *K*, Fig. 4, and turning the key until the critical line coincides with the intersection of the cross wires when the instrument is set at 1.5176.

Any transparent solid body, such as a piece of glass or quartz may be examined in a similar manner if it has two polished surfaces at right angles to each other as illustrated by the second diagram of Fig. 4.

The lower prism may be so tilted that the light reflected from the bright metal surface will enter the polished surface of the specimen normally. It is essential that the two polished surfaces intersect in a sharp edge since it is necessary that the light strikes the under surface of the specimen at grazing incidence.

From the reading of the compensator the dispersion can be estimated by means of a special table. This instrument, however, is not sensitive enough to detect small differences in the mean dispersion.

In Table III the readings of the compensator are given which were obtained for cottonseed, olive, and cocoanut oil:

TABLE III—READING OF THE ABBÉ COMPENSATOR

Oil	Scale Reading
Cottonseed	39.5
Olive	39.7
Cocoanut	40.1

The reading of the compensator for practically any liquid will fall somewhere between 39 and 41, and since the tenth part of a scale division must be estimated it is readily seen that such an instrument cannot be used for accurately determining the mean dispersion unless a very large number of observations are made. For such measurements an instrument of the Pulfrich type should be used.

University of Michigan,
Ann Arbor, Michigan.

The Santa Gertrudis Co., Ltd., reports that milling operations which were resumed on July 6, 1914, are continuing without interruption. Crushing is limited to about 85 per cent of the capacity, and it is not intended to increase this production until Mexican conditions become generally more settled and until a more certain supply of cyanide can be arranged.

Tube-Mill Tonnage Calculation

BY NOEL CUNNINGHAM

It is often difficult to determine the tonnage actually being handled by tube-mills working in closed circuit with classifiers. Where either tube-mill feed or discharge can be deflected and weighed for short periods it is still a quite inexact determination, as an accurate moisture sample is essential; and where a portion of the pulp is cut out of the flow and weighed, if the amount is sufficient to accurately determine the weight of total flow, it is next to impossible to get a close sample for moisture. In any case, only by averaging a number of weighings and moisture determinations can data of any value be obtained, and as it is an awkward, sloppy test it is not run often enough to be of real value.

The following method is, I believe, original with myself, and allows a close determination of tonnage from four screen tests which are often a part of either daily or periodic routine. The four samples required for these screen tests are: (a) Battery discharge, (b) tube-mill feed, (c) tube-mill discharge, and (d) classifier overflow.

The object of the calculation is to determine the ratio of dry tons tube-milled to dry battery tonnage. The calculation is based upon the fact that the minus 200-mesh material coming to the classifier is equal to the minus 200-mesh which leaves the classifier.

Let a = per cent minus 200-mesh in the battery discharge
b = per cent minus 200-mesh in the tube-mill feed
c = per cent minus 200-mesh in the tube-mill discharge
d = per cent minus 200-mesh in the classifier overflow
B = dry battery tonnage
T = dry tons tube-milled.

Now the minus 200-mesh material coming to the classifier is the sum of that in the battery discharge (aB) plus that in the tube-mill discharge (cT); while the minus 200-mesh material leaving the classifier is the sum of that in the tube-mill feed (bT) plus that in the classifier overflow (dB), hence:

$$aB + cT = bT + dB$$

and

$$\frac{T}{B} = \frac{d - a}{c - b}$$

= ratio dry tons tube-milled to dry battery tonnage.

Thus, knowing the dry tons passing through the battery daily, the dry tons actually tube-milled daily can be readily calculated from the routine screen tests.

It is interesting to study the limits of this ratio in practice. I should say in a general way that the minus 200-mesh in modern fine-grinding plants for the four screen tests entering into the above calculation would lie between the following limits:

	Per cent minus 200-mesh	
	Minimum	Maximum
Battery discharge	10	30
Tube-mill feed	2	8
Tube-mill discharge	35	60
Classifier overflow	60	90

The lowest value of $(d - a)$ within these limits would be 30 and the largest value of $(c - b)$ would be 58, hence within the above limits, tons tube-milled could never be less than half of battery tonnage. In the same way the highest value of $(d - a)$ within the limits above would be 80 and the lowest value of $(c - b)$ 27, or the maximum tonnage tube-milled within the above limits could not be over three times battery tonnage. Generalizing I should say that for mills where tonnage is being pushed, this ratio would be about 1.75 and never under 1.

New York City.

Comparisons of Electric Resistivities at High Temperatures

BY CARL HERING

Our knowledge of the electric resistivities of conductors at the higher temperatures, hence including those of molten metals, heated refractories, etc., is somewhat meager, although some important contributions have been made recently. In the design of those electric furnaces which are based on high-temperature resistance, these data are of considerable importance, both the absolute values of the resistivities and their comparisons. A comparative study of such resistivities might also lead to a discovery of some useful general physical law.

What meager data exists are greatly scattered in the literature; such values are sometimes given as conductivities, sometimes as resistivities, and often in entirely different units; sometimes the units are omitted entirely, this rendering the results nearly valueless. In some cases the mere resistance of a piece is given, without the necessary dimensions which would enable the resistivity (specific resistance) to be determined. In some cases true resistivities are given as "resistances," as in the French literature, for instance. Some of the data are given in curves, each with entirely different scales (for good reasons), in some cases different parts of one curve are even given in entirely different scales, even relatively different. The temperature coefficients are sometimes given in entirely different forms which in some cases are unintelligible; these coefficients and the abrupt changes during melting and vaporization are of importance as they cause some of the values to change relatively quite greatly at the higher temperatures.

A comparison of the different resistance materials, their ranges of temperature and their rates of change, both relative and absolute, therefore becomes tedious. Tabulated figures, even when well arranged, do not give the clear and direct mental picture that curves drawn to the same scale do; hence to facilitate such comparisons and to make their relative values more directly apparent, the writer has compiled what data he could find and has combined most of them in the uniform sets of curves given below, charts 1 to 5, in which all in each set have been reduced to the same scales. For more accurate values the original data should be consulted, though this is sometimes very crude, hence only roughly approximate.

When thus directly compared quantitatively, such curves show some interesting results. Moreover, as the relative values of the different materials often change very decidedly with increasing temperatures, curves are the only way to represent them directly and clearly; no tables, no matter how well arranged, could present the results so directly.

It is believed that this is the first attempt to make a compilation of this kind, and it is suggested that these charts be republished from time to time by this journal with amplifications, new data, and corrections from those who can contribute them.

The temperature scales are the same in all. Owing to the extremely wide range of resistivities, about 400,000,000, it is, of course, impossible to have them all on one chart. The scale of ordinates in each chart has been made twenty time that of the preceding one, except in the case of chart 3, in which the increase is 2500 times, there being few if any materials in that range, namely, between the metals which increase with temperature and the non-metallic materials which decrease; in general between 0.005 to 0.5 ohm. Solid graphite and carbon are more of the order of magnitude of the metals, hence are with the low-resistance materials, while silicon and powdered or granular graphite and carbon are nearer to the high-resistance group.

Some of the curves are duplicated on two successive charts so as to facilitate comparisons; but none could be carried over from chart 2 to 3 on account of the very wide range between them. The scale of chart 5 is just 1,000,000 times that of chart 1.

The observed values are shown in full lines; the dotted lines are exterpolated and should therefore be used with some reserve. It is believed that for pure metals at least all electrical resistance vanishes at absolute zero of temperature. Furthermore, recent determinations by several physicists indicate that the resistivities of some metals at least seem to increase linearly above their melting points. If these two laws, on which most of the exterpolations have here been based, are correct, the exterpolated values are probably not far wrong; and until actual determinations are made they will at least serve as probable approximations; moreover, until then they are the only data we have, and are therefore probably better than none. The writer, therefore, feels justified to make them here, even though they are not established data.

The termination of a curve with a small circle means that this is the maximum temperature at which these materials can be used, according to their makers. In the case of most of the liquid metals, their boiling points are shown by short vertical dotted lines, indicating a probable abrupt though unknown increase of resistivity; beyond their boiling points they are, of course, no longer available as liquid resistors. As metals usually go through an abrupt change of resistivity at their melting points, these latter are readily noticed on some of the curves. Both melting and boiling points are given numerically in the text in conjunction with the references. The melting points have been taken largely from the tables of the Bureau of Standards and the boiling points largely from the Smithsonian Physical Tables.

The resistivities in the text are here all given in microhm, centimeter cube units, unless otherwise stated. The conversion figures are:

resistivities in inch cube units = resistivities in cm cube units $\times$ 0.393700;

resistivities in cm cube units = resistivities in inch cube units $\times$ 2.54001.

Both co-ordinates of the present curves have been started at zero (the absolute zero, in the case of temperature), so as to facilitate direct comparisons and the finding of any general laws, if they exist.

References to most of the original sources of the data, where in some cases more detailed data may be obtained, are given below. The present writer, however, has supplemented these data with additional matter, deductions and comments, for which he assumes the responsibility.

The scale of Fahrenheit degrees is given at the top of each chart, and the scales for the values for 1-in. cube are given on the right-hand side.

For the temperature coefficient the usually adopted form is here used, namely, a in the formula $R = r(1 + at)$, in which R is the resistivity at $t°$ centigrade, r that at 0° C.; sometimes the latter is given at 20° C., in which cases 20 should be subtracted from t; but for the higher temperatures here dealt with this correction is of no importance. For the higher temperatures there is sometimes an additional factor $\pm bt^2$ in the parenthesis, but in most cases the values are not known with sufficient accuracy to warrant such refinement, hence this has in most cases been neglected here.

In some cases the curves, representing the changes with temperature, when more accurately drawn, are not quite straight lines; it may be possible that this is due to a change of volume due to expansion, or to a propor-

tionate error in the thermometer scale, or something foreign to the real resistivity.

Owing to the fact that on account of their wide range, the values cannot all be plotted on the same chart, Table I is here added, giving the materials and their values in the order of their magnitude for the different temperatures, 500, 1000 and 1500° C., which might be termed, roughly, incipient red heat, bright red heat, and dazzling white heat respectively. In some cases the values are probably only crude approximations, hence should not be relied upon as anything more than showing the order of magnitude. Those given in italics are exterpolations and are, therefore, only probable.

Vapors are used as resistors in the ordinary arcs with carbon and other materials as electrodes, the vapors then being those of the electrode materials. Also in the mercury lamp, and in Moore tubes, Geissler tubes, etc. Figures were, however, not available, it being evidently incorrect to calculate the resistance from the voltage and current, because part of this voltage is or may be a counter electromotive force, and represents (when multiplied by the current) the energy of vaporization, including what is often called the latent heat of vaporization. Very grave errors might, therefore, be made by neglecting this important factor, and it is not always an easy matter to eliminate it. In some cases, like Geissler tubes, this factor is absent, but there may then be others like contact resistance, ionization, imparting velocities to ions, etc., all of which must involve some energy consumption which would be represented in the electric circuit by a counter-electromotive force. It might be argued that a condensation of vapor occurs at the other electrode and that there would then be an equal direct electromotive force counteracting the counter one. It is a question, however, whether such condensation actually produces an emf, and, moreover, it is known that some if not most of the condensation in the mercury lamps does not take place at the electrode, but by a pure condenser action which does not return the energy to the electric circuit. And in the carbon arc much of the vapor is burned, hence its energy is lost to the

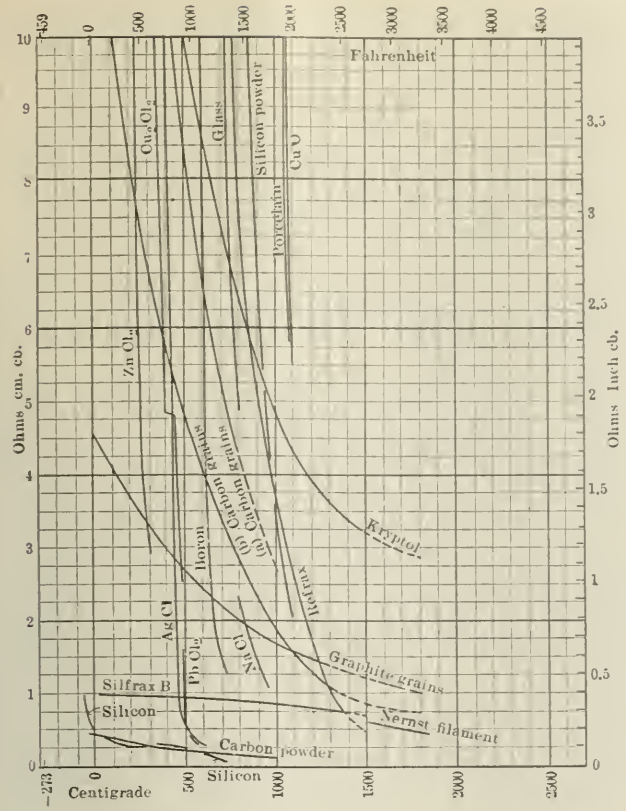

CHART 3

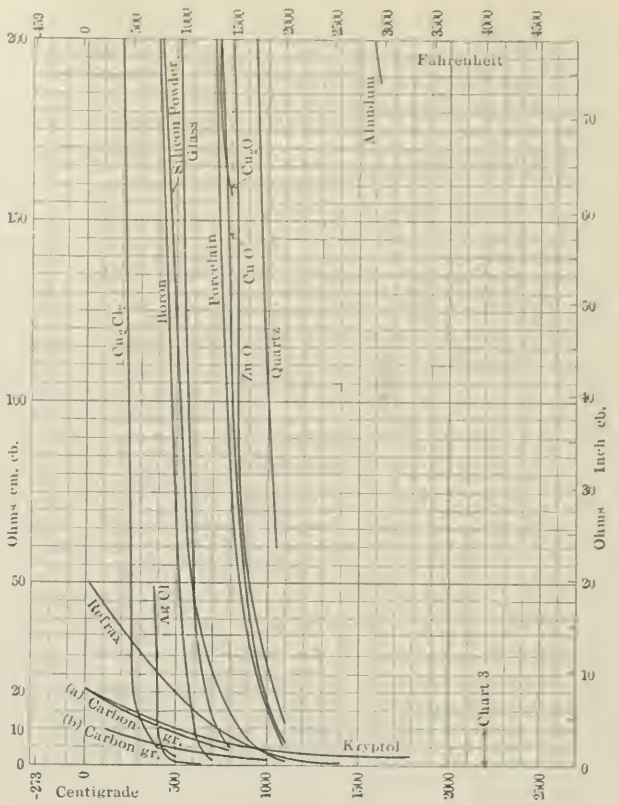

CHART 4

system. In a recent lecture Dr. Northrup announced that he expected to study this interesting question of the resistivity of vapors.

One of the curious features brought out by the present curves, if any dependence can be placed on exterpolations, is that bismuth at its boiling point may have a lower resistivity than the solid metal just before melting.

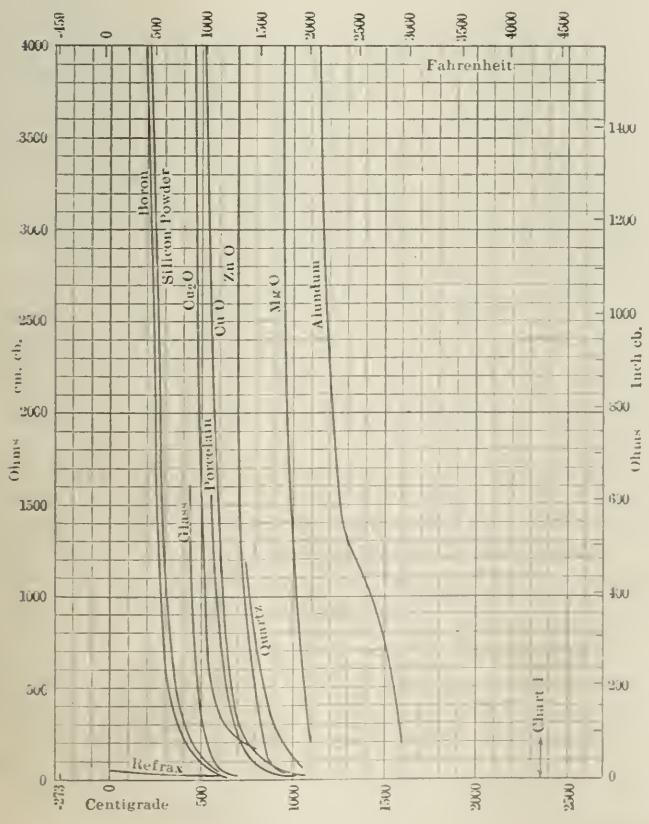

CHART 5

Northrup's recent determinations of the resistivities of molten metals, which are probably the best and most accurate, seem to have shown that these resistivities, for most metals at least, increase linearly; zinc and cadmium again are marked exceptions, behaving more like alloys than pure metal. If this linear increase is correct, interest naturally lies in seeing where these lines if prolonged downward would intersect the *X* axis, and especially whether they then meet at the same point. The present diagram enables this to be done, and it will be seen that most of them meet or nearly meet at what would be about —1600 deg. C. Tin, copper, and aluminium meet strikingly closely at this point, while gold does so quite closely, lead and silver fairly close, bismuth deviating most, though not greatly.

Northrup's values are for constant volume and are, therefore, what they purport to be, namely, the resistance of a cube of 1 cm at the specified temperature. Presumably, however, most liquid metals expand with temperature, as illustrated by mercury in a thermometer; hence if it were known at what rate they expand, it would be possible to deduce the resistivity of a constant *quantity*, weight, or mass, assuming it to expand linearly only, like mercury in a thermometer tube. Such a correction would make the lines steeper, as the resistivity would then increase more rapidly with the temperature, and these lines would then converge to a point nearer to absolute zero, but the expansion would have to be far greater than it seems to be, to bring the lines to this zero. It is of interest to note in this connection that in measuring and stating the temperature coefficient of the resistivity of solids, this factor of the change of volume with temperature is generally neglected, being too small; and when the test is made between two marks on a wire, the result is not really for constant volume but for constant quantity. A correction for constant volume might then possibly straighten out the lines of some of them which are now curved. Northrup, in a recent lecture (*Trans.*, Amer. Electrochem. Soc., Vol. 25, pages 387-8) makes an interesting comparison concerning the cubical expansion

of six liquid metals, tending to show that the ratios of their coefficients of resistance to their coefficients of cubical expansion, are nearly the same, namely, about 4.

In the discussion, Dr. J. W. Richards (page 390) makes some further suggestions concerning a possible relation between latent heat of fusion and the ratio of resistivities at the melting point.

NOTES ON THE CURVES

(Centigrade degrees and resistivities in microhm, centimeter cube units, unless otherwise stated. L. and B. means the Landolt & Boernstein tables.)

Silver. Pure. Probably very accurate determinations. Northrup. *Jour. Frank. Inst.*, July, 1914, p. 85. Melts at 960.5 deg. C. or 1761 deg. Fahr.; boils at 1955 deg. C. or 3550 deg. Fahr. At 20 deg., 1.659 microhms, cm cube; 60 deg., 1.900; 960.5 solid 8.4, fused 16.6; 1000 deg., 17.01; 1100 deg., 18.19; 1200 deg., 19.36; 1300 deg., 20.54; 1340 deg., 21.01. Increase, solid, 0.60 microhm per 100 deg.; liquid, linear increase, 1.177 per 100 deg. Temperature coefficient, liquid, 0.00069. Exterpolated to boiling point 1955 deg. C. 28.

Copper. Probably very accurate determinations. Northrup. *Jour. Frank. Inst.*, January, 1914, p. 1. Melts at 1083 deg. C. or 1981.5 deg. Fahr.; boils at 2310 deg. C. or 4188 deg. Fahr. At 20 deg., 1.7347; 1083 deg. solid 10.2, fused 21.3; 1100 deg., 21.43; 1450 deg., 24.22. Temperature coefficient when molten, from 1100 deg. to 1340 deg, 0.000381, based on 1100 deg. as the datum. Exterpolated to boiling point, 31.5.

Gold. Probably very accurate determinations. Northrup. *Jour. Frank. Inst.*, March 1914, p. 287. Melts at 1063 deg. C. or 1945.5 deg. Fahr.; boiling point not known. At 20 deg., 2.316; 1063 deg. solid, 13.50; fused, 30.82; 1500 deg., 37.0. Increase per degree when molten, 0.014142.

Aluminium. Northrup. *Transactions Amer. Electrochem. Soc.*, April, 1914, p. 380 and 388. Melts at 658.7 deg. C. or 1217.7 deg. Fahr.; boils at 1800 deg. C. or 3272 deg. Fahr. Just before fusion, 12.5; just after, 20.13; 1120 deg., 25.

Brass. Cu., 63; Zn., 34.6; Pb., 2.4. Northrup. *Met. & Chem. Eng.*, March, 1914, p. 161. Presumably carefully made determinations. Melts about 900 deg. C. or 1652 deg. Fahr. Just before fusion, 17.5; just after, 41.62; 1100 deg., 40.

Molybdenum. Fink. *Trans. Amer. Electrochem. Soc.*, Vol. 17, p. 229. Melts at 2500 deg. C. or 4500 deg. Fahr. Annealed, at 0 deg., 4.8; hard, 5.6. Temperature coefficient per degree, 0.0050.

Tungsten (a). Fink. *Trans. Amer. Electrochem. Soc.*, Vol. 17, p. 229. Melts at 3000 deg. C. or 5430 deg. Fahr. Annealed at 0 deg., 5.0; hard drawn, 6.2. Temperature coefficient per degree 0 to 170 deg. C., 0.0050.

Tungsten (b). Pirani. *Tables Annuelles*, Vol. 1, p. 227. Old lamps. Gives ratios at various temperatures up to 1500 deg. C., to value at 20 deg. C. Latter here assumed to be 5.55 as given by him, p. 220.

Cadmium. Probably accurate determinations. Northrup. *Jour. Franklin Inst.*, February, 1913, p. 153. Melts at 320.9 deg. C. or 609.6 deg. Fahr. Boils at 778 deg. C. or 1432 deg. Fahr. At 0 deg., 7; at 321 deg., solid, about 17.1; liquid, 33.77; 700 deg., 35.78. Exterpolated to boiling point, 36.5.

Platinum (a). L. & B. Melts at 1755 deg. C. or 3191 deg. Fahr. At 0 deg., 11.0. Temperature coefficient, $a = 0.00394$, $b = 0.000000584$, between 0 deg. and 500 deg. C. The exterpolated values are probably only very crudely approximate.

Platinum (b). Pirani. *Tables Annuelles*, Vol. 1, p. 227. Gives ratios at various temperatures up to 1600 deg. C., to values at 20 deg. C. Latter here assumed to be 9.6 as given by him, p. 219.

Tantalum (a). Siemens. Melts at 2850 deg. C. or 5160 deg. Fahr. At 0 deg., 14.6. Temperature coefficient in per cent per degree 0 deg. to 100 deg., 0.33; 100 deg. to 1850 deg., 0.29.

Tantalum (b). Pirani. *Tables Annuelles*, Vol. 1, p. 227. Gives ratios at various temperatures up to 2000 deg. C., to values at 20 deg. C. Latter here assumed to be 14.6. At 2000 deg. it is 92.5.

Zinc. "Reagent zinc." Probably accurate determinations. Northrup. *Jour. Frank. Inst.*, Feb., 1913, p. 153. Melts at 419.4 deg. C. or 786.9 deg. F. Boils at 920 deg. C. or 1688 deg. Fahr. At 0 deg., 6; at 419 deg. solid, 17; liquid, 37.3; 850 deg. 35.74. Exterpolated to boiling point, 36.

Tin. Nearly pure. Probably very accurate determination. Northrup. *Jour. Frank. Inst.*, Feb., 1913, p. 153. Melts at 231.9 deg. C. or 449.4 deg. Fahr.; boils at 2270 deg. C. or 4118 deg. Fahr. At 0 deg., 11; 225 deg., 22; 235 deg., 47.60; 750 deg., 61.22. Liquid, linear increase, 2.61 per 100 deg. Exterpolated to 2000 deg., 93.8.

Iron (a). Melts at 1520 deg. C. or 2768 deg. Fahr., probably meaning pure iron; boils at 2450 deg. C. or 4442 deg. Fahr. This curve gives only crude approximations; pure iron being never used, accuracy is of no importance. The resistivity at zero was taken as 8.56 for pure iron as a mean of two values in L. & B. The rise with temperature based on that at zero was taken from the curve by Somerville, *Physical Review*, Vol. 31, p. 268, which values appear to have been determined with care, but they are unfortunately not given either as resistivities nor even in ohms, but merely relatively. The value when molten is a crude determination by the writer, of ordinary steel. The rise after melting is mere exterpolation, based on the general converging lines of other metals, no importance should be given to it. The bend in the curve at the point of recalescence is of interest.

Iron (b). Vom Baur. Molten iron and steel. No temperature given.

Ferro-nickel. 50 + 50. L. & B. at 0 deg., 36; 600 deg., 100; 1000 deg., 105.

Rose Metal. L. & B. Melts at 94.3 deg. C. At 0 deg., 64.5; at 93.5 deg., 78; at 250 deg., 80.4; at 350 deg., 83.3. The small fall at the melting point is exterpolated from the curves before and after; it may not be correct; it contains much bismuth which has a very great fall at its melting point.

Lead-Tin Alloy. 75.78 Pb, 24.22 Sn. Mueller. *Tables Annuelles*, Vol. 1, p. 222. Congeals at 263.8 deg. C. At this temperature 73.2; at 1000 deg. C., 98. Note that though an alloy the line seems straight.

Lead. "Test lead" free from silver. Probably very accurate determinations. Northrup. *Jour. Frank. Inst.*, February, 1913, p. 153. Melts at 327.4 deg. C. or 621.1 deg. Fahr. Boils at 1525 deg. C. or 2777 deg. Fahr. At 0 deg., 24; at 327 deg. solid, about 49.2, liquid 94.7; 800 deg., 116.20. Exterpolated to 1000 deg., 125, to 1500 deg., 148.

Calido. Elec. Alloy Company. Melts above 2800 deg. Fahr. or 1530 deg. C. Wire 0.010 in. diameter has 5.75 ohms per foot. Temp. coeff. 0.00019 deg. Fahr.

Krupp Metal, Nickel Steel. Thomas Prosser & Son. Maximum safe temperature 600 deg. C. or 1112 deg. Fahr.; at 20 deg,, 85.13. Temperature coefficient, presumably from 0 deg. to 600 deg. C., 0.0007007.

Woods Metal. L. & B. Melts at 69.8 deg. C. or 157.5 deg. Fahr. At 0 deg., 51.8; 50.3 deg., 57.8; 75 deg., 85; 350 deg., 109.5. Note that it rises considerably at the melting point, although it contains much bismuth.

Nichrome II. Driver-Harris Company. Maximum safe temperature 2000 deg. Fahr. or about 1100 deg. C. At 20 deg. C., 660 ohms per mil-foot. Temperature coefficient, 0.00009 per Fahr. deg.

Bismuth. Nearly pure. Probably very accurate determination. Northrup. *Jour. Frank. Inst.* February, 1913, p. 153. Melts at 271 deg. C. or 520 deg. Fahr.; boils at 1430 deg. C. or 2606 deg. Fahr. At 17.5 deg., 120; 271 deg. solid 267, liquid 127.5; 750 deg., 153.55. Exterpolated to boiling point 191.

Mercury. L. & B. Melts at —40 deg. C. or —40 deg. Fahr.; boils at 357 deg. C. or 675 deg. Fahr. At —183.5 deg., 6.97; at —40 deg., about 29; at 350 deg., 135.

Antimony (*a*). Nearly pure. Before fusion the values are only approximate. Northrup. *Jour. Frank. Inst.* February, 1913, p. 153. Melts at 630 deg. C. or 1166 deg. Fahr.; boils at 1440 deg. C. or 2624 deg. Fahr. At 650 deg, 117.07; 900 deg., 131.0. Exterpolated to 1000 deg., 158.

Antimony (*b*). Bornemann & von Rauschenplat. *Tables Annuelles,* Vol. 3, p. 258. Only after fusion. Exterpolated to boiling point, 145.

Graphite (*a*). Acheson Company. At 20 deg., 0.000320 ohm, inch cube. Resistivity according to Northrup, increases about 9 to 10 per cent from 20 deg. to 1500 deg., and more rapidly thereafter. Exterpolated part continued to the graphitization point here assumed roughly as about 0.0013 at 3300 deg., where this curve should meet those of carbon.

Graphite (*b*). Hansen. *Trans. Amer. Electrochem. Soc.,* Vol. 16, p. 329. Here based on his percentage values, p. 334, and what he seems to assume as the mean room temperature value, p. 339, namely, 0.00035 ohm, inch cube.

Carbon (*a* and *b*). National Carbon Company. Fine-grained electrodes (*a*) 20 deg. C., 0.0014 ohm, inch cube; 400 deg., 0.0011; 800 deg., 0.0010. Coarse-grained electrodes (*b*) 20 deg. C., 0.0020; 400 deg., 0.0015; 800 deg., 0.0014. At higher temperatures they say it changes by a linear function to the graphitization point, here assumed roughly as about 0.0013 at 3300 deg., hence the exterpolated curves have here been continued to this point where the curves should meet those of graphite.

Carbon (*c*). Somerville. *Physical Review,* Vol. 31, from the apparently well-determined temperature curve on p. 270, where, however, the values are only relative; 0.0038 ohm was here assumed as the basic value at zero, as he gives no actual resistances.

Carbon (*d*). Hansen. *Trans. Amer. Electrochem. Soc.,* Vol. 16, p. 329. He calls attention to the variability of the resistivity of cold carbon, depending upon what temperature it had been raised to while in use, the higher temperatures graphitizing it more or less. The present curve is the "parent curve" in his Fig. 3, based on the value 0.00137 ohm, inch cube, cold, which he seems to have used.

Carbon Grains (*a*). National Carbon Company. Sifted through 4 mesh and resting on 6 mesh, not tamped. At 20 deg. C., 8.2 ohms, inch cube; 800 deg., 1.7.

Graphite, Carbon (*b*) *and Kryptol Grains.* Jeffries. METALLURGICAL & CHEMICAL ENGINEERING, March, 1914, p. 154. Grains passing through 0.093-in. mesh and remaining on 0.0328-in. mesh. No pressure.

Silicon. Zimmerman. *Tr. Am. Electrochem. Soc.,* Vol. 15, p. 395. Very variable. Resistivity decreases rapidly with increase of temperature. Melts at about 1430 deg. C.

Carbon and Silicon Powders. Somerville. METALLURGICAL & CHEMICAL ENGINEERING, August, 1912, p. 484. Passed a 40-mesh screen. Column under about 3 lb. pressure. Results given as curves only. The carbon powder had about fifty times the resistivity of solid carbon, and the powdered silicon about 25,000 times that of solid silicon. Powders were placed and measured in porcelain tube. The present curve for porcelain (by the same author), however, shows that at the higher temperatures the resistivity of the tube was of approximately the same order of magnitude as that of the silicon powder, hence it would seem that the error introduced by the tube must have been quite great.

In the *Electrical World,* May 25, 1912, p. 1118, the same writer gives measurements on carbon and silicon powder the size of sand to fine dust, under various pressures. Carbon under no pressure, about 0.20 ohm; hence about fifty times that of solid carbon. Silicon under pressure of about 30 kg per sq. cm about 0.40 ohm; under no pressure it has about 500,000 times the resistivity of solid silicon. No curves are here given, as the data were all determined at room temperatures.

Silfrax B. Carborundum Company. Maximum safe temperature about 1800 deg. C. At 20 deg. C., 1.0 ohm, cm cube; 1400 deg., 0.7.

Refrax. Carborundum Company. Maximum safe temperature about 2100 deg. C. At 25 deg., 50 ohms, cm cube; 1400 deg., 0.65.

Nernst Filament. Wurtz. *Trans. Am. Inst. Elec. Eng.,* Vol. 18, p. 545. Length, 25 mm; diameter, 0.63 mm; 196 volts, 0.5 amp, hence 0.49 ohm, cm cb. No temperature given.

Zinc Chloride. $ZnCl_2$. L. & B. Melts at 262 deg. C. or 505 deg. Fahr. At 230 deg., infinity; just melted, 4.46 ohms; 310 deg., 290; results not very concordant.

Silver Chloride. AgCl. L. & B. Melts at 460 deg. C. or 860 deg. Fahr. At 380 deg., 47.6 ohms; 500 deg., 0.547 ohm; 650 deg., 0.214 ohm.

Copper Chloride. Cu_2Cl_2. L. & B. Melts at 434 deg., C. or 813 deg. Fahr. At 140 deg., 1000 ohms; 250 deg., 29 ohms; 400 deg., 4.83 ohms; 440 deg. (melted), 4.79 ohms; 490 deg., 2.52 ohms. Note that the resistivity appears to remain nearly the same for a while about the melting point.

Lead Chloride. $PbCl_2$. L. & B. Melts at about 500 deg. C., 932 deg. Fahr. At 500 deg., solid, 0.824 ohm; 520 deg., melted, 0.418; 580 deg., 0.372.

Sodium Chloride. NaCl. L. & B. Melts at 790 deg. C. or 1454 deg. Fahr. Freezing, 2.28; melted at 960 deg. C., 1.087.

Boron. Weintraub. *Trans. Amer. Electrochem. Soc.,* Vol. 16, 1909, u. 165. Only approximate. Melts at 2000 to 2500 deg. C. At 23 deg., about 1.7 megohms; at dull red heat, here taken as about 700 deg., a certain piece had a resistance of about 5 ohms, which would be roughly about 1.5 ohms, cm cube. The present curves are in a range where but few values were given by him, hence indicate but little more than the general order of magnitude.

Glass, Porcelain and Quartz. Somerville. *Physical Review,* Vol. 31, 1910, p. 261. Presumably good determinations. No figures are given for resistivities, only curves. Good data for temperature coefficients. Berlin porcelain begins to soften at about 1100 deg. C. It seems that all three of these materials were still solid over the ranges given. For quartz, the logarithm of these resistivities plotted against temperatures, gives a straight line. The values for glass plotted as conductivities do not give a straight line.

Various oxides in powder form. CuO, Cu_2O, MgO, ZnO, Fe_2O_3, and MnO_2. Somerville. METALLURGICAL AND CHEMICAL ENGINEERING, July, 1912, p. 422. The curves in the original article give the actual resistances and not the resistivities, although not so stated. They are here reduced to resistivities, and are only approximate, as accurate data for the reduction were not given. Pressure 2 to 4 lb. on a column 1 cm diameter. The powders were measured while in porcelain or quartz tubes, but as the present curves show that the latter materials have resistivities of about the same order of

magnitude at the same temperatures (according to the same author) an error of considerable magnitude must have been involved, hence they may not even be of this order of magnitude; the tests were therefore like measuring the resistivity of mercury in a copper or iron tube. The present compilation brings out just such features. The values for Fe_2O_3 and MnO_2 were so nearly like those for ZnO that the curves have been omitted. CuO melts at 1084 deg. C. or 1984 deg. Fahr. (almost exactly the melting point of copper); Cu_2O decomposes at 800 deg. C. or 1472 deg. Fahr.

Alundum. Grade RA 355. Al_2O_3. Fused bauxite. Northrup. METALLURGICAL AND CHEMICAL ENGINEERING. February, 1914, p. 125. Presumably a reliable determination. Melts at 2050 to 2100 deg. C. At 1600 deg., 190 ohms.

Philadelphia, Pa.

Has Titanium Any Influence on the Properties of Steel?

BY F. A. J. FITZGERALD

For several years the writer has frequently been asked the question: "Has titanium really any influence on the properties of steel?" The question has invariably been answered in the affirmative because of the evidence furnished by actual experiments and that gleaned from the voluminous and apparently trustworthy literature on the subject. For some reason, however, there undoubtedly exists a great deal of scepticism on the subject.

The reason for this scepticism is not very difficult to find for it obviously lies in certain characteristics of the manufacture of steel which are analogous to the older practice of medicine, a practice which indeed may exist in some quarters even to this day. There used to be, in the old days of medical practice, a wonderful form of treatment known as the "blunderbuss prescription," which consisted of as many constituents as the ingenuity of the doctor could combine with due consideration of the laws of compatibility. Usually there could be no question whatever as to the effect of the exhibition of the medicine as a whole, but for obvious reasons it was extremely difficult to separate the reactions of the various constituents. Now to the layman it certainly appears that the doctoring of steel is often governed by the methods of the blunderbuss school, and to this is added a large number of accidental occurrences which certainly influence the final product, and consequently make it extremely difficult to correlate various causes and effects.

No one watching a series of heats run off in a steel mill can fail to recognize the number of things happening during the manufacturing process which must affect the steel ingots. The temperature of the metal involves generally the personal equation of the melter, the rate at which the moulds are filled is apt to vary, there may be running stoppers, the way in which the steel is doctored by sundry additions varies. In the case of small heats you may sometimes see a melter make additions of substances which he conceals about his person and which may or may not influence the final result. Under such conditions it might be expected that the final product of the manufacture will show considerable variations when different heats are examined, and this is certainly found to be the case.

Probably no one will deny that it would be a great advantage if we could use perfectly pure and suitable materials for the manufacture of steel, melt these under uniform and perfectly controlled conditions and so eliminate the objectionable doctoring of the metal, whether by the blunderbuss or more scientific methods. This, however, is unfortunately impossible and, therefore, since doctoring must be done it should be as nearly scientific as possible. There cannot be any doubt at all that the great difference of opinion as to the effect of various additions used in the manufacture of steel is due to the ways in which the medication is exhibited and to the attention to or disregard of the laws of compatibility. Even when a single steel mill, where a more or less uniform practice is followed, is considered, it is impossible to avoid many variables, so that in order to arrive at conclusions about the effect of any one addition, such as titanium, it is necessary to make a sort of statistical investigation.

An article which recently appeared in the *Railway Age Gazette*[1] mentioned some tests which apparently would lend themselves to an inquiry of this sort, and the Titanium Alloy Manufacturing Co. allowed the writer to examine a number of records covering these tests. From these data were obtained which on analysis seem to show beyond a doubt that the addition of titanium to steel has an important influence on its properties. The data are derived from very complete reports on 155 heats, representing the production of over

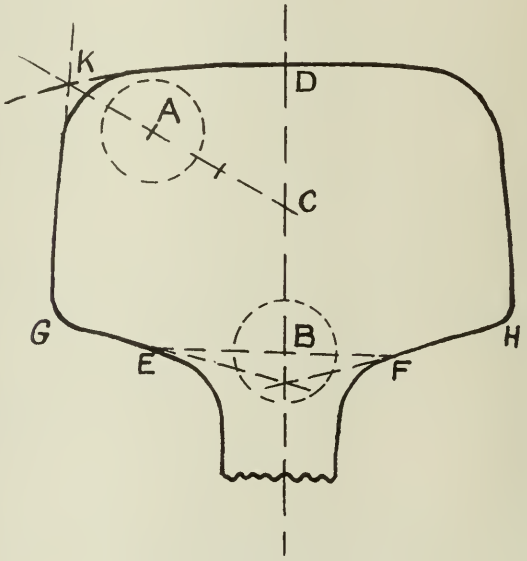

FIG. 1—SECTION OF RAIL

9000 tons of 100-pound steel rails, all made at the same mill and under as uniform conditions as could be expected. In 78 heats no addition of titanium was made, while in 77 heats ferro-titanium was added in the ladle. Here, then, there appears to be a sufficient number of observations on a large enough scale to eliminate to a great extent the effect of variable errors.

As everyone knows, the rail problem is a very serious one and an immense amount of study has been devoted to its solution. It seems to be believed by a great many authorities that segregation is one of the chief causes of trouble, and with this in view a method of detecting segregation has been proposed for use in the specifications for rails. Referring to Fig. 1, which represents a section of a rail, drillings are taken at places indicated by the circles A and B. The centres of B and A are found respectively as follows:

The points E and F are where the lines G E and H F leave the edge of the section. The line E F is drawn and bisected at B, which is the centre of the circle.

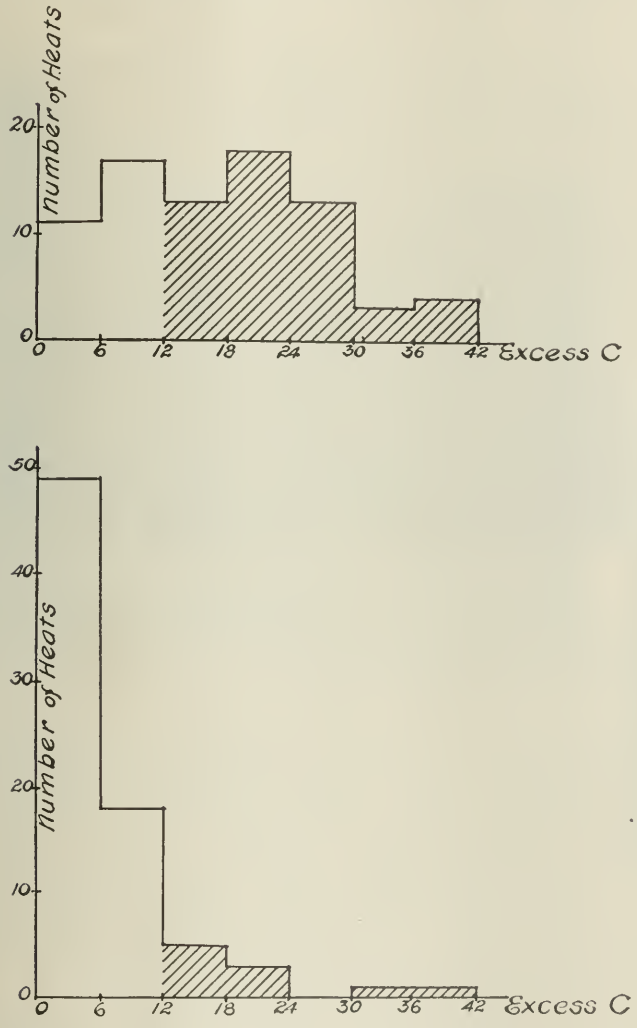
The line B D is drawn along the axis of symmetry of the section and bisected at C. The point K is the intersection of the prolongation of the curve D K with the line G K. Join C and K and then the centre A is found at two-thirds of the distance of C from the intersection of C K and the edge of the section.

[1]October 23, 1914.

The samples for analysis are made with a ⅝-in. drill and used for carbon determinations.

In the proposed specifications these samples are taken from A rails, i.e. the first rails made from the heads of the ingots after a 9 per cent crop. In general the carbon in the sample at B is found to be higher than that in sample A and it is suggested that whenever the carbon in B is more than 12 per cent greater than that in A the rail should be rejected. In the 155 heats under consideration this method of testing was used, since it was maintained that the use of titanium diminished segregation. Accordingly from every heat the Titanium Alloy Manufacturing Co. took the nineteenth ingot for applying the test and the Steel Co. took the eighteenth for a check test.

There are various ways in which the results obtained may be shown, but they are best illustrated by the diagrams of Fig. 2. In order to make the diagrams the various heats were divided up into seven groups as follows:



FIGS. 2 AND 3—DIAGRAMS OF RESULTS OBTAINED WITH HEATS OF STEEL WITHOUT AND WITH USE OF FERROTITANIUM

Group No.	Per cent excess of C. in web
1	6.0 or less
2	6.1 to 12.0
3	12.1 to 18.0
4	18.1 to 24.0
5	24.1 to 30.0
6	30.1 to 36.0
7	36.1 to 42.0

The number of heats falling in each group was then determined and from these the diagrams were drawn. The upper diagram shows the results obtained in the 78 heats where no titanium was used and the lower diagram the results from the 77 heats where titanium was used. In each case the shaded portion shows the heats where the carbon is in excess of the limit set by the proposed specification.

The test shows that where no titanium was used only 36 per cent of the heats gave A rails which came within the proposed specification limits, while with the use of titanium 87 per cent. would pass.

A more detailed examination of the 77 heats in which titanium was used clearly shows the influence the amount of titanium added has on the results. According to the advice of the Titanium Alloy Manufacturing Co. the amount of ferro-carbon-titanium used should be such that the quantity of metallic titanium added to the steel is 0.10 per cent. This, however, was not followed as in some heats only 0.075 per cent was added and in some as little as 0.053 per cent. The following table shows the effect of the amount of titanium added:

Titanium added. Per cent	Total Heats	Heats within specification limit. Number	Per cent
0	78	28	36
0.053	7	3	43
0.077	39	33	84
0.10	31	31	100

This seems to show that in order to get the best results at least 0.10 per cent of metallic titanium should be added.

While it may be argued that, as regards the amount of titanium which should be added, it is necessary that a larger number of experiments be made to determine the proper dose, there cannot be the least doubt that the question originally asked must be answered in the affirmative.

The FitzGerald Laboratories, Inc.,
Niagara Falls, N. Y.

Findings of the Selby Smelter-Smoke Commission

The Selby Smelter Commission appointed to settle the controversy between the Selby Smelting & Lead Company and the residents of Benicia, Cal., and contiguous agricultural territory, has filed its report with the Superior Court of Solano County, Cal. The commission comprised J. A. Holmes, director of the U. S. Bureau of Mines; E. C. Franklin, professor of organic chemistry, Leland Stanford, Jr., University, and Ralph A. Gould, chemical engineer, of San Francisco. The purpose of the commission was to determine whether the smelter was operating in violation of the court decree of July 16, 1908; the extent of violation, if any; and the manner of operation necessary to avoid violating the decree. A large corps of experts was employed to make various investigations. The commission has found that the smelter violated the decree with respect to damage to certain horses up to April, 1914, at which time a bag-house was installed and operated. No violation is found with respect to disagreeable odor, or as to damage to vegetation. It is stated further, that the decree will not be violated if less than 80 tons of SO_2 is discharged into the air in 24 hours. One of the interesting findings of the commission was to the effect that sulphurous gases from Dwight-Lloyd roasters could be concentrated by recirculation to the extent of 7.5 per cent SO_2, making it possible to produce sulphuric acid from the gas.

Missouri led all other states in the production of lead and zinc in 1913, according to figures compiled by the U. S. Geological Survey, although the production for the past year was less than that of 1912 due to a smaller output of zinc and decline in price for that metal. The total value of lead and zinc concentrates in 1913 was $21,109,358. Based on metallic content, the value was $29,494,064.

The Hardwood Distillation Industry in America*

BY EDWARD H. FRENCH AND JAMES R. WITHROW

In view of the economic importance of the utilization of wood waste, and the increasing interest being manifested in this utilization, it naturally surprises the inquirer that there is practically no literature upon this industry from the point of view of actual American practice. It may not be without value, therefore, to consider the progress made in hardwood distillation and to trace its development from its inception in this country. We have gathered together consequently and classified much of the information which we have acquired in the plants of this industry during an experience in its totalling about twenty-five years.

This tracing of the development of an industry of the magnitude of this one is peculiarly interesting to the engineer, since it shows the necessarily slow evolution of the industry in the hands of the unscientific manipulator, and serves to emphasize the advantages with which the modern chemical engineer is possessed, and serves also to indicate how much more rapid the development might have been in the hands of experienced chemical engineers. It indicates also that the future may, under the direction of the competent engineer, make advances of importance much more rapidly than in the past. This latter statement is significant when it is remembered that the advances made thus far have been due either to accidents or very often to workmen endeavoring to minimize the laboriousness of their work. As plants are operated on 12-hour shifts, this desire to economize energy may be readily understood.

For much of the historical information collected we desire to express our appreciation to Mr. Robert Mackay, who has been active in this industry for so many years. In fact, during the past fifteen years our own continued intimate acquaintance with Mr. Mackay has been not only of unusual pleasure but of continuous instruction. A history of this industry would be incomplete without mention of the fact, that due largely to his personality and integrity, the firm with which Mr. Mackay is identified, has had the unusual experience, in an extensive industry, of supplying engineering materials for every plant of this nature in the United States and Canada with perhaps two exceptions, for a period covering the past 25 years.

Early History

While charcoal burning was doubtless carried on in the earliest days in this country it was not until 1830 that James Ward began the manufacture of pyroligneous acid, at North Adams, Mass., according to Monroe and Chatard (12th Census, United States, Bull. No. 210, Chemicals and Allied Products, p. 34). No claim is made that the pyroligenous acid was carried further, though it may have been. We have ourselves no information on this matter other than the above citation. As far as we can ascertain it was not until 1852 that works in the modern sense were inaugurated for the distillation of wood for the production of volatile products, and their semi-refined products. This does not appear in agreement with W. L. Rowland (Special agent 10th U. S. Census on Chemical Products and Salt, p. 23) who is later cited by Monroe and Chatard (Ibid) and C. L. Campbell, METALLURGICAL AND CHEMICAL ENGINEERING, 1910, p. 155, all of whom state that the manufacture of acetate of lime and methyl alcohol was started in the United States about 1867 by James A. Emmons and A. S. Saxon in Crawford County, Pa. Our information in this case comes from various manufacturers who have been in this business from the earliest times or at least whose family connection with it goes back to the beginning. One of these sources is Mr. Neil Patterson, whose father was in charge of the original "Scotch Works," built in 1852. In this year The Turnbull Company of Glasgow, Scotland, who were engaged there in the copper and iron industry as well as that of wood distillation, built the first operation in this country, by way of expanding their old country business. The place chosen for this location was known as Milburn, New York, now Conklins Station, on the D., L. & W. R. R. not far from Binghamton.*

This Turnbull company brought with them their apparatus as well as men experienced with their methods. On account of these Scotch workmen the works became known as the "Scotch Works" and this name has clung to it to the present time, although the original workmen gradually went with new operations which started

FIG. 1—TYPICAL WOOD YARD IN PENNSYLVANIA

shortly after this one. They had much to do with the subsequent expansion of the industry, all of them being later in charge of new works.

It is interesting to note in connection with this first plant that it was a type that was copied in detail in the construction of those that followed, for many years afterward. All these plants were equipped with cast-iron cylinders 42 in. in diameter and 9 ft. long, set in pairs, thus each pair held about 1¼ cords of wood. The wood was cut 7 ft. long and the charge "run off" every 12 hours, and six days a week. The stills and pans were operated during these early days exclusively by direct firing. The fuel used for the retorts, stills and pans was the charcoal produced, over which was poured the residual tar to make a quick fire.

This original works was followed in 1865 by Emmons & Co., of Brookdale, N. Y. In 1868 Alonzo Smith started a plant at Sturroco, Pa.; Keery Brothers, Cadosia; Mandaville, Emmons, Corbett & Mitchell, Livingston Manor, N. Y.; King & Co., Acidalia, N. Y.; Hilton & Co., Hiltonville, N. Y.; Brand & Schlayer; Frink & Ross; Tyler & Hall; Inderlied & Co.; Bayless & Berkalue and Wright & Co. were also early in the field.

During the early part of this period of development the chief product desired was acetate of lime, for which from 12 to 15 cents per pound was obtained. The alcohol demand was almost negligible, that which was made was of very infeior quality and was kept in barrels, and most of it was lost by evaporation or through some "illegal vent." The charcoal also had but little commercial

*A paper read before the Philadelphia meeting of the American Institute of Chemical Engineers on December 4, 1914.

*Mr. J. L. Stuart, of Corbett & Stuart, one of the earliest firms in this business in this country, informs us that the date 1852, given by Mr. Patterson for the building of the Turnbull plant, should be 1849.

value and was largely consumed as fuel at the works, although a small local demand gradually developed starting with the neighborhood tinsmith.

The change from the old charcoal heaps or pits to the kilns probably came quite early and perhaps before any of the improvements we have mentioned. It was not until 1876, after the retort system was well established and markets for its products had been developed, however, that Dr. H. N. Pierce's inventions made it possible to utilize partially the products wasted in the smoke from the charcoal kilns in Michigan, where great quantities of charcoal were prepared for blast furnace use.

The earliest attempt at refining alcohol, so that it might be of commercial value, was made by a Mr. Pollock, a chemist living just out of New York City. In a short time a demand began to develop for this product, which steadily increased, and up until 1880 was at all times up to the dollar mark. It was during this period that the need of better refining was felt, as it was realized that a large loss was entailed in the refining operations. This necessity accounts for the coming of the Burcey pans in the early seventies. These are copper containers placed in the vapor line above the stills, with

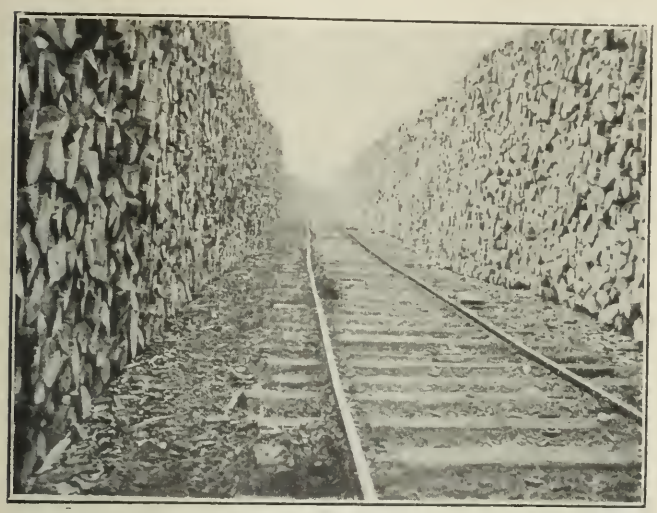


FIG. 2—CLOSE VIEW OF WOOD YARD

deflectors inside to project the vapor against the upper shell of the container, upon which a stream of water runs, causing fractional separation of the water from the alcohol vapor. The increase of alcohol product resulting from this improvement, together with the increasing market demand, made a central refinery necessary, and the producers united in building a refinery at Binghamton, N. Y., known as the Burcey Refining Company. This was in the middle seventies, and the plant is still in operation. It has served a good purpose, and to it was due perhaps more than to anything else the substitution of steam for direct fire distillation.

Before leaving this early history, it should be mentioned that the Turnbull plant, and, in fact, several succeeding plants, had but four pairs of retorts or 5 cords capacity to the charge, thus by obtaining two charges within twenty-four hours their total wood consumption was about 10 cords per day. To-day there are single plants operating 160 cords daily. Thus we have an illuminating comparison, at least so far as size is concerned, of the development of the industry.

Design of Apparatus

Even at the present time, there remain many plants using the old original retort system, with one very slight modification. Those first in service were of cast iron, while the later ones have shells of steel with riveted cast-iron necks and fronts. The purpose of this change was due to the fact that in the early operations, since the wood was then of much less value than later, and high yields were not so important, it was charred at a very high temperature, in order to increase as much as possible the capacity of the plant by shortening the time of firing. As cast iron was much more durable for these high temperatures than steel, this use of cast-iron retorts was universally practiced. When, however, with the coincident rise in the cost of wood, it was found that lower temperatures gave an increase of all products, it was seen that steel could be employed to advantage, for its lower weight permitted the turning of the retort. This turning refers to the saving in apparatus universally practiced and consists merely in the removal of the brick setting when the side in contact with the fire becomes buckled, rolling over the retort, and placing the uninjured part next the fire, thus materially increasing the life of the retort. This modern retort is of uniform size and design in all plants which still use this type of apparatus. The shell, as originally, is 42 in. in diameter and 9 ft. long, supported at the ends in a cast-iron cradle and having a cast-iron front, with door and lugs for pinning the door shut. At the rear is a neck 10 in. in diameter with attached condenser.

The evolution of the condenser is especially interesting, in view of the fact that when the original condenser was installed each succeeding plant accepted it as being of proper size, and the new installation was made the same size. Then from time to time some one would discover that an addition would yield more product and at once the arbitrary sized unit was changed.

FIG. 3—LOADED WOOD CARS AT OVEN

Originally the worm condenser was used, but it soon became apparent that the heavy carbon bodies caused clogging, and soon the log condenser was substituted and was used until the introduction of the upright tabular one. These log condensers were made by attaching, by a copper tee, a large-sized copper pipe, called the log, to each pair of retorts. Near the ends of this pipe were copper connections, joining the large log to a smaller one, and this in turn was similarly connected with others progressively decreasing in size. The whole log condenser lay in a plane at an angle of 45 deg. and the whole was surrounded by a wooden box with water inlet at bottom and outlet at the top. The joints were simply slip joints and were slipped together and "sweeled"; that is, wrapped with a cloth liberally covered with red lead, which after becoming dry or "set" offered a suitable and effective joint. At the ends of the logs were removable slip joint caps, for cleaning purposes, thus the cleaning from the heavy tarry and carbonaceous bodies was easily accomplished.

The first really important change in the general style of operation was that of replacing the old retort by the oven, which was done in the middle nineties, and is claimed to have been first tried out at Straight Creek, Pa. This change was wholly mechanical, and consisted merely of substituting for the retort a large rectangular oven, equipped with rails on the bottom for the purpose of carrying cars. These cars were loaded with wood and could be quickly pulled in and out mechanically and the charcoal unloaded outside the oven, greatly increasing the economy in this part of the operation over the slow hand drawing of the charcoal of the retort system.

There appears to be, however, much more advantage in this style of operation than the mechanical advantages which were at first anticipated, as an increased yield of products is obtained, due undoubtedly in part to more advantageous manipulation, but in our opinion also to the different chemical reactions that take place. In the old retort system complete carbonization of the wood took place in about sixteen hours, and it required in the oven system twenty-four hours, yet the temperature of the gases at the neck are higher in the latter, running at a maximum under skilful manipulation to about 330 to 360 deg. C., while in the former case the operation was consummated at not over 290 deg. maximum. This maximum temperature is obtained about midway or two-thirds of the run, at which time a very decided exothermic reaction takes place, and care must be exercised that the liquor is not "burned"; that is, that the temperature is not permitted to rise, so as to avoid undue formation of condensation products, which would be immediately seen in an increased flow of gas and a darkening of the crude liquor. This exothermic reaction, which also takes place in coal distillation, probably accounts for the increase in temperature of the uncondensed gases in the oven system, since no greater proportionate radiation takes place in this system than in that of the retort construction. At this particular stage, on account of the nature of the source of the heat (exothermic changes in the wood) a much more uniform temperature throughout the oven is maintained. This gives an excellent illustration of the possibility of considerable alteration even in the chemistry involved in a process when we change the mechanical manipulation.

An additional advantage obtained by this oven system is that the charge of residual charcoal may be drawn while the oven is still hot, thus economizing on the fuel necessary for reheating, while a partial cooling is necessary in the hand-drawn retort system.

The time lost during this cooling was saved in one design at Dahoga, Pa., where the retort at the conclusion of firing was removed by a crane from its vertical setting and replaced at once by a previously charged retort. It is stated in the meagre literature on this industry that "this type is probably most used."* This Dahoga installation, though it operated for many years, was the only plant that ever was installed in this country so far as we are aware, and certainly there is little likelyhood of any existing now, for this one was recently converted into an oven plant.

There is still a third system, which should be at least mentioned, namely, the kiln system. This was really the second in date of development, but the oven system was so closely allied in design and operation to the original retort system that the two were taken up together. The fact is, we would expect the logical development to have been: Charcoal heap—charcoal pit—charcoal kiln—by-product charcoal kiln—retorts—ovens, but this does not appear to have been the case, in this country at least. As in the coke industry we do not appear to have gone from bee-hive oven to by-product bee-hive oven, directly, but through the by-product oven, an outside and distinct invention, so in this industry charcoal kilns were only converted to the by-product kiln system after the development of the retort system.

When charcoal was produced in kilns, from 20 to 86 cords of wood were placed in a kiln constructed of bricks, and wood was used as fuel for carbonizing. The volatile products were lost through the opening provided at the top. With the advent of markets for alcohol and acetate some charcoal manufacturers placed a pipe connecting this opening with a suction fan and a condenser and thus collected the volatile products. The amount of product thus recovered is but a fraction of that recovered in a retort or oven system. In Pierce's system the flat-topped circular kilns usually hold 50 cords. They are heated by gas burned in a furnace under the kiln. For the sake of brevity, a description of these interesting kiln plants will be omitted since their recovery of by-products is low and they are confined almost exclusively to the blast furnace plants of Michigan, where they are steadily and rapidly being displaced by oven plants.

Yields

The low yield from the kiln system, which runs about 100 lb. of acetate of lime and 4 gal. of alcohol per cord, together with the low yields obtained by *rapid or quick* firing plainly show that there is a mean temperature

FIG. 4—A PENNSYLVANIA 66-CORD PLANT

which gives the maximum yield. Just what the curve of efficiency is, to our knowledge, has never been definitely determined in a commercial plant, though we have given it much experimental attention and others doubtless have worked on it also. In fact, there are so many factors to be considered in a comparison of experimental operations on a commercial scale that while the factors causing increased or lessened results are known, it is difficult to obtain accurate definite knowledge as to just how much each factor contributes to the results. For example, we know that Michigan plants under approximately the same construction and operation obtain less product per cord than those of New York and Pennsylvania without certain knowledge of the relative influence of the various contributing factors.

This lack of definite data on a commercial scale, so deplorable in most industries, results from the difficulty of obtaining successive tests with all conditions alike, for we well know that any variation, for instance, of temperature, has a peculiar relation to the results obtained. In addition it goes without saying that the variety or species of the wood enters largely into the

*Met. and Chem. Eng., 1910, p. 155.

results obtained, and even the part of the tree used may cause variation. For example, a charge made up wholly of heart-wood will give better yields under the same conditions than a charge of slabs, making due allowance for the bark. Again we have found that weight for weight, cord-wood obtained from the mature or virgin trees will yield higher than the small second growth; also we are convinced of a noticeable difference in results from wood of the same species grown on high and dry places, and that from low or marshy soil, the latter giving a slightly lower yield. Indeed it is interesting to hear the experienced operator maintain that wood cut in the winter months will give better results than if cut while the sap is running. We are, however, unable to verify this expression, and it is possible that some other factor may have been responsible for this often-repeated statement. It is also held by many operators that eliminating the consideration of extra fuel necessary for the charring of green or unseasoned wood, the results are not the same in finished product as from well-seasoned wood. We can see from these statements that with so many factors to be considered, it is extremely difficult to determine which enter most into the discrepancies between the various systems; retort, oven, and kiln. However, from the purely practical standpoint we do know that there is a marked difference between yields obtained from the different systems as well as from the two general localities extensively operating.

FIG. 5—START OF OVEN PULLING

If we compare the results obtained by the same system operated in the Allegheny Mountains with that of the Lake Superior region, we find that by taking the results on a yearly basis from a well-operated plant and calculating the wood on a basis of a cord 8 in. by 4 in. by 52 in., there should be obtained conservatively 216 lb. of 80 per cent acetate of lime, 11.3 gal. of 82 per cent crude wood alcohol, and 52 bu. of charcoal. The yield from the Lake district is slightly under this in alcohol, and decidedly so in the acetate yield, which is 175 lb. to 180 lb. on continued operation. However, here again we have at least two factors and it is difficult to determine their relative influence. First, in the Eastern field, beech predominates, while in the other hard maple is in larger proportion, and also slab wood is used much more largely. In fact, we have been unable to obtain data from a continued operation in which at least a small proportion of slabs was not used.

Construction

At this point it may be well to take up the question of construction, especially of the most successful and modern system, that of the oven, which is, with the exception of the mechanical manipulation, similar to the retort system.

The ovens are of uniform height and width, in most plants being 6 ft. 3 in. wide and 8 ft. 4 in. high, the length determining the capacity, running from 26 ft. to 54 ft. and holding from 5 to 10 cords. The steel used in the shell is usually $\frac{3}{8}$ in., while the bottom and back heads are of $\frac{1}{2}$-in. material. Ovens are built either with doors at both ends in order to withdraw the residual charcoal coincidentally with refilling the oven with wood-loaded cars, or in many cases, with a door at one end, the oven being loaded after the charcoal has been run into the coolers. In any event the door is hung upon a cast-iron frame riveted on the oven. This frame has a groove of about 1 in. for the use of asbestos packing and the cast-iron door is hung to the frame by riveted cast-iron hinges. The oven is stiffened by means of angle irons riveted perpendicularly on the sides, and on one side near the top are riveted 30-in. cast-iron nozzles, usually two in number, to which are attached the condensers.

The first ovens installed were placed upon piers in the setting, upon which were iron plates and rollers to accommodate expansion of the oven, but in the later settings the ovens are suspended from tee rails laid across the brick setting at the top and supporting the oven by means of U-bolts riveted thereto. The bottom of the oven is equipped with clips for holding the rails which carry the wood cars. These cars vary but slightly in length in different plants, running from 10 ft. 4 in. to 12 ft. 4 in. inside length and about 78 in. high, thus each car holds from 2 to $2\frac{1}{2}$ cords of 52-in. wood. Each has four 18-in. wheels with roller bearings running on 2-7/16-in. turned steel axles.

Immediately in front of the ovens are two charcoal coolers arranged in series and approximately of the size of the ovens. Into the first the hot charcoal is drawn from the retort, where it stands for twenty-four hours. From this cooler it is drawn into the second one for another twenty-four hours of additional cooling. These coolers are made of very light iron with cast door frames riveted on each end, and light sheet-iron doors. No bottoms are required as the coolers are simply placed on the ground and banked along the sides and doors with loose dirt.

To the nozzles heretofore mentioned are connected the condensers. These are upright tubular condensers, made with copper hoods having a removable head and are bolted to gun-metal heads which are bored for the copper tubes, usually $1\frac{1}{4}$-in O. D. seamless copper, and expanded into these gun-metal heads, the whole surrounded by a steel water-jacket with water inlet at the bottom and outlet at the top. Connected to a bottom pan bolted on the lower head is a goose-neck trap for trapping off the non-condensible gases, thus separating them from the pyroligneous liquor, which is run into a wooden tank. The gas from the charge is carried into a main gas line which runs to the boilers where the gas is injected under them by a small steam jet. This jet performs the additional and very important function of serving to reduce any back pressure on the ovens, thereby preventing leaks. In order to prevent this suction from becoming too pronounced and drawing over the lighter volatile products through the condenser into the gas line, a butterfly or clapper valve is arranged on the line and regulated by a spring so set

that any undue suction opens the valve, thus relieving the line.

Primary Distillation Operation

After this general outline of the first stage of the construction let us follow the operation to this point. After the loaded cars are run into the ovens the doors are pinned shut with taper pins driven into lugs which are a part of the casting of the door frame. The fires are started under the ovens and in about an hour the water distillation and first dissociation begins, the distillate being of a very light yellow color and having a tannin-like odor, and running about 2½ per cent of acid during the first hour when well-seasoned wood is used. Gradually this acid content rises until at about the fifteenth hour, when the content should be running from 12 to 14 per cent. After a few hours' running a small percentage of light tar begins to appear and steadily increases until at the latter end of the run tar is by far the larger constituent of the distillate. The acid content of the watery constituent gradually diminishes until it is almost negligible.

The product obtained under the usual practice, with average wood of at least a year's seasoning, is from 215 to 220 gal. of crude pyroligneous product giving an

FIG. 6—CHARCOAL COOLERS. A NEW YORK PLANT

acid titration of 8 to 8½ per cent and an alcohol content of 4 to 4½ per cent. The tar yield is from 22 to 25 gal. to the cord, with a residual charcoal in the cars of about 52 bu. of 20 lb. each. With green or unseasoned wood the total distillate is diluted and will run from 275 to 325 gal. of liquid.

In the early stages of the run the non-condensible gases are largely air and carbon dioxide. Therefore for the first few hours, and even after much of the hydrocarbons and carbon monoxide are accumulating in the gases they have no fuel value. However, the percentage of carbon dioxide diminishes rapidly, and from the middle to the end of the run the oven gas has an important fuel value. The total amount of gas will run from 11,000 to 12,000 ft. per cord.

As we have already intimated, the influence of the temperature of dissociation is extremely important, and the yields are much dependent upon its regulation. For example, if during the height of the run the temperature at the neck of the oven materially exceeds 750 deg. Fahr. much greater volumes of non-condensible gases are being formed, together with an excessive amount of tar, and it is quite possible to lose from 5 to even 10 per cent of charcoal, together with a serious loss both of alcohol and acid content. Rapid firing, however, without reaching excessive limits will materially increase the acid content at the expense of the alcohol, while slow, even firing, operating the oven at a period in excess of the usual twenty-four hours, will increase somewhat the alcohol production and lessen that of the acid.

The interesting results obtained from excessive firing arise, as we hope to show later, both from a difference in the chemical dissociation and also from the subsequent formation of condensation products.

In drawing the hot charcoal from the ovens, quantities of combustible gas remaining in the ovens would cause explosion on the opening of the doors. This is obviated by the introduction of live steam into the front of the oven for a short time before the drawing is made.

Handling the Crude Distillate

The crude distillate or pyroligneous acid, called in the works "raw liquor," is first pumped into a series of wooden settling tubs, connected with brass piping. The first tub, where the greatest amount of tar settles, is connected near its top with an overflow pipe to the secong tub. The second tub is connected with the third by a pipe somewhat lower, and this series of drops is continued so that the last tub is drawn from within about 18 in. from the bottom. The raw liquor thus settled free from tar is, as a rule, continuously run into the copper stills. These copper stills are for the purpose of distilling off the lighter volatile products away from the tars and oils which remained in solution in the settled liquor. They are from 7 to 10 ft. in diameter with proportionate height, made of 12 to 14-gage cold-rolled copper, and equipped with a steam coil, usually of 3-in. or 4-in. seamless drawn copper tubing and starting from about 18 in. from the top and running helically around the walls and on the bottom to midway between the center and pheriphery. For a 2000-gal. still from 300 sq. ft. to 400 sq. ft. of heating surface should be used. In addition each still should be supplied with a live-steam jet applied at the bottom and preferably through a copper ring having small steam openings.

After a copper still has run continuously for some time it gradually becomes filled with deposited tar and its flow of distillate diminishes. When this has reached a stage of very slow production, as it does every four days, the feed valve is closed and the live steam jet is opened, distilling the tar with live steam, thus obtaining considerable quantities of acid and light oils. This latter distillate is run into separate tubs, where the light oil on the top is withdrawn before the acid liquor is pumped into the original copper still distillate which has been run into a wooden "mixing tub." The tar from the settling tubs is usually distilled in a separate tar still, sometimes made of wood, and distilled as has been that just described. This practice is followed as it permits the separation of the oils independently and without allowing them to come in contact with the original distillate, in which a portion would dissolve, thus the bulk of the distillate contains less impurities by this practice.

The mixing tub is usually from 12 to 14 ft. in diameter, and 4 ft. high, having a very heavy wooden stirring arm fastened to the end of a heavy shaft, operated by a slow moving gear at the top. Slacked lime is slowly added to the liquor in the tub, which contains its own indicator, the liquid changing at the neutral point to a pronounced wine color. For maximum yields, however, the addition of lime, probably owing to the acetic esters present, should be continued until this color has been followed by a yellowish one and until a bead appears or bubbles form on the surface and which disappear slowly. A very small further addition

of lime at this point causes the acetate to stick to the pans when evaporated and prevents satisfactory crystallization. Under-neutralization also causes inferior quality in crystallization, and before final drying the acetate has a decidedly black color instead of a rich yellow brown, and there is an accompanying loss in product owing to the esters lost.

From the mixing tub the neutralized liquor is jetted or run into an iron still known in practice as the "lime lee" still. In a few plants this is equipped with either Burcey pans, or in some more modern works with a fractionating column, although most plants do not fractionate at this point. The customary practice is simply ordinary distillation. The crude alcohol starts over at about 20 per cent on a Tralle scale, but quickly rises to 35 per cent and at times 40 per cent, gradually dropping in percentage to from 15 to 20, at which strength it continues for some time and then drops rapidly to 5 per cent or 6 per cent, at which point it seems to hold stationary again for a long period. After all of the alcohol has been distilled over, a valve in the vapor neck is closed and the residual acetate solution is blown, by means of live steam pressure applied in the still, to an iron settling pan above the top of the

FIG. 7—DUMPING CHARCOAL

ovens, where the excess lime and insoluble impurities settle out in a few hours. The acetate liquor is then drawn into flat steam pans having a jacketed bottom for steam supply, the pans usually being about 16 ft. long by 8 ft. wide and 18 in. deep. Here the acetate liquor is boiled rapidly until crystals appear on the surface near the edges, when the steam is reduced so that the crystalline film which forms at once on the top does not break, which would cause it to fall to the bottom and form a hard crust. Care must be exercised in this "seeding" process, as it is called, or a great quantity of this exceedingly hard crust or scale will be produced, which is unfit for the market. After this "seeding down" has continued until the whole mass in the pan has reached a very thick mushy consistency, it is shoveled out on the acetate or "kiln floor," which is a smooth brick or tile covered floor over the top of the ovens. Here the acetate is continually turned until dried and ready for sacking and shipment.

The "weak alcohol" from the "lime lee" still, containing from 9 to 12 per cent of acetone and alcohol, is accumulated and distilled in an iron still having either 5 or 6 Burcey pans or a column. This distillate is the final crude product produced by the works, and is usually shipped to a central refinery, although a few plants refine their own product. In this distillation all the product coming over above 60 per cent is run into the storage tank, and the lower fraction is put back with the lime lee distillate for further distillation. The finished crude is sold on a basis of 82 per cent and contains about 16 per cent acetone.

Returning to the copper still residue, the tar from these stills, as well as that from the tar still, is run into a sump and from there jetted under the boilers for fuel. The two fuel products, gas and tar, furnish approximately 35 per cent or 40 per cent of the necessary fuel for all operations.

Before leaving this subject of operation it might be said that many of the earlier plants omitted this copper still distillation, neutralizing the raw liquor directly after settling and thereby obtaining the "brown acetate" of commerce, which is to-day practically without market. This brown acetate runs from 60 per cent to 65 per cent acetate.

Production Costs

The costs of producing the products above mentioned have been on a constantly increasing scale, owing in a large measure to the increasing cost of cord-wood and stumpage. During the past fifteen years in the eastern district, stumpage in suitable location has been sold for as low as 15 cents per cord, while to-day 75 cents to $1 is the approximate average. The cost of cutting varies from $1.15 to $1.35 per cord in fair timber, and in scattered timber $1.50 is sometimes paid. To-day, including transportation, piling, etc., this will make the cost on board oven cars $4 to $5 per cord, though wood is being put in for as low as $3.50 by users of mill-waste or by those having long standing holdings.

This gradual rise in the cost of wood is due to natural causes, among which are the increase in stumpage cost due to the ever-decreasing supply, and the natural rise in labor, together with increased length and cost of transportation. With the exception of one possibility, there appears to be no hope of any future lowering of costs. This one exception, a new cord-wood splitting machine, appears from our examination to have merit, and presents an entirely new system of cord-wood production. It is generally conceded that cutting and hauling the large log is less expensive than cutting and handling the cord-wood at the stump. The tree is therefore cut in logs and large limbs and transported to the machine, where a slide carries it first to a cross-cut saw, which cuts it into the proper lengths. The sawed pieces continue to a platform where they are either split in halves or quartered by one blow. The split wood automatically moves by a slide to the railroad car or wagon. It is claimed that under suitable conditions 50 cents per cord, or in some instances even more, may be thus saved. We have been unable to see continued operations of this machine as yet, and consequently cannot verify this saving cost, but are inclined to believe that at least some reduction in wood cost is possible by this means.

The cost of fuel for a crude works, in addition to the tar and gas used, of course varies with the available supply. In the New York and Pennsylvania districts,

TABLE I—PRODUCTION COSTS PER CORD OF WOOD

Wood (maximum) per cord	$5.00
Fuel	1.15
Labor	1.25
Lime, 0.96 bu. at 19 cents	.18
Bags (acetate)	.14
Freight (acetate, 16 cents per 100)	.35
Freight (alcohol)	.10
Selling commission acetate	.11
Insurance, per cord	.068
Taxes, per cord	.112
General expense	.57
Total	$8.85

when coal is used, this cost will amount on an average to $1.15 per cord, and when natural gas at 15 cents per thousand feet is used the cost is but slightly more. The labor at the plant is usually counted at $1.25 per cord.

The summation of production costs given in Table I (p. 35) will be generally accepted as a fair basis in considering investment in new installations.

Production Values

With the present slump in markets the values herein set down are low, especially that for acetate of lime. The past 10-year-average would be about $2 per hundred, while at present the market is slow at $1.75 per hundred.

Alcohol (82 per cent), 11. gal. at 25 cents	$2.75
Acetate of lime, 216 lb. at $1.75	3.78
Charcoal, 52 bu. net at 6¼ cents	3.38
Total crude value	$9.91

This gives a production cost of $8.85 and a sales value of $9.91 per cord. It will be noted that no selling costs except in the case of acetate of lime have been included, because in the works not refining or making the finished products, which are in number far in excess of those who do refine, the alcohol is sold under contract to the refiner, and the charcoal is either, as in the case of those plants in the Lake district, consumer at iron furnaces in connection with the plants, or as in the eastern field handled by a general sales agency controlled by the manufacturers, proportionately to their daily production capacity, yielding to the producer about the above mentioned figure at present.

These production costs are based on the yields in the eastern field, which, as pointed out, were higher than those of the Lake region. This discrepancy is compensated however by the fuel wood costs being lower in the Lake region, owing to the fact that in most instances mill-waste is used. The general relation between the two fields of operation in this production cost and product value is therefore approximately the same. It is undoubtedly true that many manufacturers can show much greater net profit than the above figures indicate, because of cheaper wood and fuel, and in some instances because of plant design.

Costs of Installation

Eliminating the cost of wood supply, $2,000 per cord per day production is counted as a reasonable installation cost for a plant as described, for producing crude products. For instance, the cost of boilers, ovens, cars, coolers, pumps, etc., is substantially $650. Copper work, including stills, condensers, piping, etc., approximates $450. Brick work for ovens and boiler setting, etc., will come to about $190. These three general items are more or less about a fixed estimate, varying, of course, somewhat upon the price of materials at the time. The location, buildings and general costs vary with the design and the desire of the builder. However, the above stated general figure of $2,000 is a fairly accurate estimate, unless elaborate construction is undertaken.

Large Scale Experimentation

Realizing the possibilities and necessity of counterbalancing the increasing cost of production, several large operators have made extensive large scale experiments with a view of increasing yields and saving production costs. Unfortunately the results obtained thus far have not justified the expenditures made in spite of many optimistic claims (Met. and Chem. Eng., 1913, p. 434), owing in a measure to the many unlooked for complications which arise between the laboratory and the works scale. Of the great amount of work which has been done along this line with which we happen to be familiar, space permits the citation of but a few illustrative instances.

In the fall of 1908 certain men largely interested in the business went to Germany to investigate developments there and returned with a process for eliminating the copper stills and making gray acetate of lime directly from raw liquor, a proposal which had already been made and studied in this country. This process had been reputed to be in successful operation in Germany. It was in fact merely the application of the cup column to the neck of the ovens. The cups and openings were of course of larger size than in the customary column, but in effect this really was all that could be claimed for the new appliance. It was held that the pyroligneous vapors, passing through the condensed

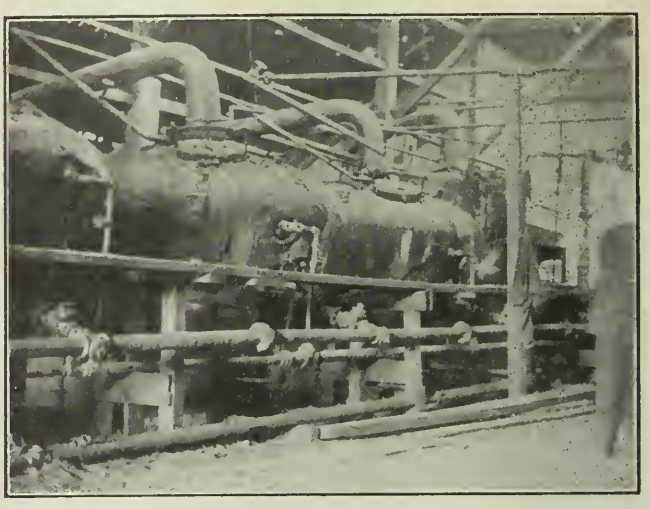

FIG. 8—ANCIENT TYPE OF COPPER STILLS, FORMERLY DIRECT FIRED, THEN CONVERTED TO STEAM HEATED BY A NOW DISMANTLED RETORT PLANT

tarry liquor, were freed from their impurities by this means and that gray acetate could be produced from the resulting raw liquor by direct neutralization. Educated or impressed by the then incomplete American investigations mentioned, these men permitted themselves to be carried away by the assurances of the German engineers and, as has happened several times in our industrial chemical development in more or less identical circumstances, without adequate experimental investigation they equipped a large plant with this apparatus at an enormous expense, the copper work for which alone exceeded $80,000. The plant did not prove satisfactory.

It will at once be seen from foregoing statements in this article, that there were two fundamental reasons which explain, in our opinion, the failure to obtain the desired results. First, as pointed out, mechanical clogging of the apparatus would occur, as was the case in the original worm condenser; and second, as we believe, the valuable products readily form condensation products with the unsaturated hydrocarbons and aldehydes present in the distillate. Certainly the passing of these vapors through the hot tarry liquid would tend to increase this chemical reaction. Moreover, the apparatus caused back pressure on the ovens and required a suction to overcome this objection. This increase of suction would tend to bring the vapors through the cups and the condensers at a more rapid rate, which of course would lessen their efficiency.

Later another process, also brought from Germany, was tried, which was in effect the same as the one

above described, except that the vapors were forced through a body of hot tar for the purpose of washing them, but this also was not successful. In our opinion this was for the same fundamental chemical reason as mentioned above.

A process for accomplishing this result, but not as yet entirely developed, from which some very satisfactory results have been obtained, is based upon a totally different theory from those mentioned. This method places a fractional condenser on the neck of the oven, which is maintained at a temperature sufficient to liquify the high boiling tars and oils. These, however, are largely mechanically carried along by the uncondensed and non-condensible gases, while a part of the tar is run off through a goose neck on the bottom of the fractional condenser, the uncondensed vapors and the non-condensible gases with their suspended tar and oil liquids are carried into the bottom of a centrifugal basket or drum, installed in a copper container and having small perforations inside of the drum, which is supplied with wings to give a rapid motion to the gases. This centrifugal action throws the liquid particles or mist against the side of the container, on which are deflectors set at an angle opposite to the

FIG. 9—SODA STILLS. WOOD ALCOHOL REFINERY

direction of the moving drum. Thus the condensed bodies are forced to the bottom of the container and out of the zone of circulation, through a goose neck into the tar receiver, while the vapors continue to a second condenser and are there condensed, the wood gas being trapped off in the usual manner.

This process has given uniformly increased yields of product, but exact data as to saving, yields and cost of operation have not been determined as yet. A little over one horsepower is necessary for the operation of a 7-cord machine until speed is attained, then three-fourths hp. is necessary.

The increase in product yield with this method is probably due to the fact that the vapor contact with the condensed and unsaturated bodies present is reduced to a minimum.

Another attempt at fuel conservation, which it seems should be possible of accomplishment, relates to the evaporation of the acetate liquor. As has been seen, much heat is necessary for evaporation of this liquor, and this method attempts to utilize the high temperatures of the gases at the oven's neck before they enter the condensers. We are not aware of any installation of this nature, although patents have been issued for accomplishing this end. Nevertheless, as it involves what appears to be a wholly mechanical manipulation there should be no great difficulty in saving at least a portion of this waste heat. Here again it can be seen that experimentation to accomplish this end is costly, since all experimental changes necessitate considerable financial outlay if tried on a large oven, and also involve interruption of regular operation which must from time to time inevitably occur.

Under this head of experimentation may properly come an elaborate attempt to utilize hardwood sawdust for alcohol manufacture. This was undertaken in 1903 by a well known lumber company in Cincinnati, who endeavored to destructively distill sawdust continuously by means of an endless belt which carried the sawdust through an oven for the purpose of carbonizing, tapping off the pyroligneous vapors and obtaining an uninterrupted production of charcoal, which was briquetted. The distillate was handled in the usual manner.

It can be readily seen that sawdust can not be destructively distilled in bulk, as is cordwood, for the insulating space between the particles prevents the heat from going through the mass. This explains the reason for the endless belt.

No expense was spared either in buildings or equipment, the buildings being of stone and the equipment of the best; the whole costing probably $200,000. Notwithstanding this outlay the operation was a complete failure, the plant being dismantled within a year and the buildings used for other manufacture. The high fuel cost in attempting to overcome the resistance to radiation in such a mass was an important item in the high production cost which resulted in the failure. In addition, sawdust charcoal is a more dangerous fire risk than common charcoal, in the handling of which in the ordinary plant special arrangements are necessary.

Within the past five years some plants have installed double and triple effect evaporators with a view of fuel economy and reports as to the results are very contradictory, but the continued use indicates at least partial success. One Michigan plant is successfully drying its acetate with a drum and belt dryer. Vacuum drying for acetate has been tried, but we are unaware of any success, as the resultant product is a powder which the market demands the crystal.

Refining

From the time of the formation of the already mentioned Burcey Refining Company, the usual plan of manufacture contemplated only the production of the crude product as described, selling the product, those of the Eastern field, largely to a Buffalo refinery, and the Michigan manufacturers to Detroit, and up until the passage of the Denatured Alcohol bill by Congress they received a price usually ranging from 40 to 75 cents a gallon for the crude alcohol. After the passage of this act, and with the purchase of the Detroit plant by the one at Buffalo, the price of crude was at times as low as 15 cents per gallon, and during this period of adjustment intense depression prevailed amongst the crude producers, as it was feared that ethyl alcohol would largely supplant methyl. It was found, however, that the trade, particularly the paint trade, preferred wood alcohol even at a slightly higher price, and this fact virtually saved the industry. With the formation of a refining company among eastern crude operators representing somewhat over 1000 cords daily production, and the erection of a refinery at Olean, N. Y., the monopolistic control of refining was immediately reduced. A very acceptable dead rental was paid to the crude producers for their uncompleted refinery, as well as a substantial increase for their crude product, which eventually reached and is maintained at about 25 cents per gallon of 82 per cent product.

The method first employed by refiners was merely that of fractional distillation, and we all perhaps will remember the yellow, ill-smelling wood alcohol of commerce. Later, and for a long time, bleaching powder and sulphuric acid were used before the final distilla-

tion. This materially improved the product, but with the improvement of the columns used, treatment with sodium hydroxide and distillation is all that is necessary. The NaOH serves the purpose of polymerizing the aldehyde impurities. It also saponifies both the tarry matter and esters. The formerly objectionable acetone present, which distills with the heads, now has its own market value under the name of acetone-alcohol and is used in varnish removers, as a solvent in the rubber and other industries and also as a carrier for acetylene gas in lighting systems. Thus this 16 to 18 per cent of impurity is now in fact an added value to the refiner.

Markets

Prior to the present unfortunate European situation the average production of acetate of lime from the manufacturers in this country amounted approximately to 7000 tons monthly, and we are informed that the total European and Canadian production is almost equal to this, of which tonnage Austria-Hungary furnished about two thirds. The plants in Europe, however, are usually on a very small scale in comparison with those in this country. Sweden alone has plants of a size in

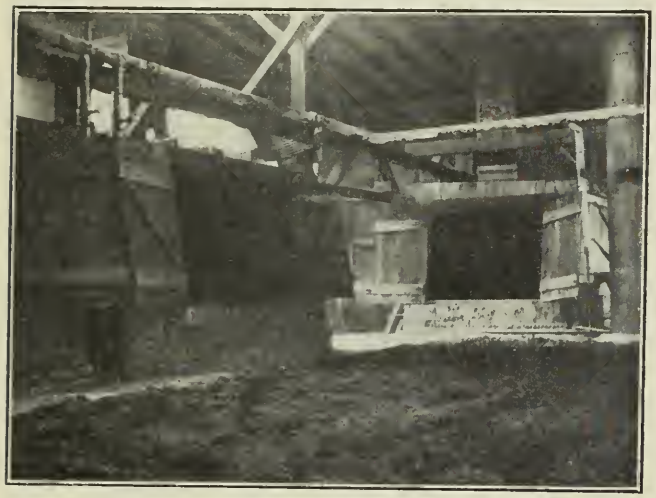

FIG. 10—ACETATE PANS AND KILN FLOOR

anyway comparable with the larger ones here. Of the production of acetate in this country, from 50 to 60 per cent is exported, a considerable percentage to or through Belgium. Of course, it will be understood that these statements refer to the market situation before it became demoralized by the European war, although for a year prior to the declaration of war there had been a pronounced stagnation of the markets both at home and abroad.

Of the acetate of lime consumed in this country, by far the largest percentage goes into acetic acid production. The hardwood industry is therefore vitally connected with this acetic acid industry, and one of the most important developments in the last decade is the successful beginning made in combining the crude manufacture and this refined or finished product manufactured in the same plant. Such combination plants have shown crude acetic acid yields in continuous operations running 92 to 96 per cent of theory, using 5 per cent sulphuric acid in excess of that theoretically required, and giving on a continued daily production of 4000 pounds, with a yield of 91 per cent of the possible theoretical yield, refined acetic acid of the finest double distilled quality.

The chief individual acetic acid market demands in this country are from the manufacture of white lead, paint colors, the textile and leather industries, although in the aggregate the small consumers such as the laundries, ink and drug trades, consume great quantities. This country prohibits the manufacture of acetic acid vinegar, but its production is permitted abroad.

The consumption of export acetone produced in this country is chiefly by England, and Italy is just now a large consumer. The industry is in a particularly thriving condition at the present time owing to its use in production of explosives for the European war. There should be obtained 20 to 22 pounds of acetone per 100 pounds of acetate used, and in connection with the crude works acetone production is very profitable, as the general operating expenses are low. Of course its use in this country was very large for explosive manufacture and for the production of chloroform under the well known Rump patents, regarding which there was so much patent litigation some years ago and which as you know were upheld. In comparatively late years, however, a large Michigan concern has produced chloroform commercially from carbon tetrachlorid, which has probably influenced somewhat the acetate consumption for this manufacture. There are four plants in the United States producing acetone for the market and within the past week ground has been broken in Pennsylvania for a fifth plant. There is but one plant operating in Canada, to our knowledge.

Ten years ago the steel industry consumed by far the major percentage of charcoal produced. This percentage however has decreased considerably owing to the improved methods for steel production. Many industries such as cutlery and car wheel manufacture demanded charcoal iron, but in these and many other instances coke iron has been substituted. This falling off in the proportionate use of charcoal in iron production has been made up in an increased domestic demand. Charcoal is now sold in small paper sacks in many cities for use both in hotels and private families.

The production of crude wood alcohol amounts to between 10 and 11 million gallons per year, and of course it has innumerable uses, including that of the paint industry, which is the largest single user.

Space will not permit in a general article such as this, of going into details regarding production and markets of the other products such as formaldehyde, creosote, etc., which are directly or indirectly derived from hard wood distillation.

Distribution of Plants

Although not in agreement with any published figures, we place the distribution of distillation plants as follows:

Michigan	8	oven plants carbonizing	1032	cords daily
	5	kiln plants carbonizing	1050	cords daily or
	13	plants carbonizing	2082	cords daily
Pennsylvania	33	oven plants carbonizing	1424	cords daily
	13	retort plants carbonizing	215	cords daily or
	46	plants carbonizing	1639	cords daily
New York	7	oven plants carbonizing	256	cords daily
	17	retort plants carbonizing	362	cords daily or
	24	plants carbonizing	618	cords daily
Wisconsin	2	oven plants carbonizing	96	cords daily
	1	oven-kiln plant carbonizing	250	cords daily or
	3	plants carbonizing	346	cords daily
Kentucky	1	oven plant carbonizing	20	cords daily
West Virginia	1	oven plant carbonizing	49	cords daily
Tennessee*	1	oven plant carbonizing	32	cords daily
Vermont	1	retort plant carbonizing	16	cords daily

This makes a daily capacity in this country of 2909 cords in 53 oven plants; 593 cords in 31 retort plants and 1300 cords in 6 kiln plants or a total of 4802 cords in 90 plants.

In Canada there are 9 oven plants charring 424 cords daily and one retort plant charring 48 cords, or a total of 472 cords in 10 plants. This makes a total for America of 5274 cords per day in 100 plants.

*A recently constructed 16-cord retort plant now being converted into an oven plant.

These figures will mean more to us if we remember that 5000 cords of wood represent a pile 4 ft. high and 52 in. wide and 7.5 miles long, weighing when seasoned approximately 10,000 tons.

These figures show the importance and size of the industry in this country.

Conclusion

It will be evident that the chief economic drawback in the present manufacture is the fact that most of the plants do not manufacture the finished products, thus in general it may be inferred that two sets of freight charges, commissions and handling expenses are required before the products reach the consumer. For instance, with acetate of lime at $2 the net return to the producer is about $1.75 per hundred.

A large part of this difference could easily be saved by undertaking the manufacture of the finished product at the crude plants.

Hitherto such combinations of crude and finished product manufacture have been thwarted in the majority of cases by an almost complete monopoly of the finished products by certain groups of chemical manufacturers, who by various manipulations maintained control of markets, or who were able to dominate the situation, as in the case of acetic acid, by their regional control of sulphuric acid manufacture, or even attempted control of pyrites importation. The violent market fights which have developed because of these facts have

FIG. 11—THE COLUMN WALL IN WOOD ALCOHOL REFINERY

been carried through successfully in more than one instance by the crude manufacturer, because of his advantageous situation, and it is certain that these attempts, therefore, to thwart the natural economic development of this industry will sooner or later collapse to a great extent, or the refiner will be compelled to either go into the crude business himself or combine with the crude manufacturer.

We have attempted to show the difficulties met and the expensive experimentation that has been undertaken in the past for the improvement of this industry, and have pointed out some of the results thus obtained. When it is remembered that German statistics claim that but one of fifteen serious trials of new chemical processes are successful and that this percentage amply pays for the losses entailed in the fourteen unsuccessful ones, it can be seen that while these expenditures are individually unfortunate, in the aggregate this law of averages will probably hold good in the development of this industry for its economic position demands the solution of the problems indicated.

Columbus, Ohio.

The Natural Chill of Cast Iron and its Significance in the Manufacture of Malleable Castings

BY GRAFTON M. THRASHER

Some years ago the author of this article became impressed with the growing need for more light on the subject of iron mixtures generally. All published articles on this subject laid heavy stress upon the adjustment of the silicon with more or less vague statements as to what the proper percentage should be in various castings.

Many very arbitrary and conflicting statements were made by different writers and investigators which were very confusing to one in search of fundamental facts.

During the intervening years much has been done to clear up what were once great mysteries to the foundryman, but it seems that while we have collected an immense amount of data, yet very little of it has been coordinated in such a manner as to make it valuable to the foundryman; and the mixing of iron, while practically all done by chemical analysis at the present time, is largely done by formula or pattern mixture without a definite knowledge as to whether it is the best suited to the work or not.

Several years ago while the author was engaged as chief chemist for a prominent and long-established malleable iron company, it occurred to him that the mere regulation of silicon was not sufficient to produce the desired degree of chill.

While the author has often noticed this phenomenon before in connection with cupola iron it was only after being repeatedly impressed with it in the case of both, open-hearth and air-furnace metal that it occurred to him that variations in the total carbon was the principal cause of disturbance and after some thought on the matter it was decided to run total carbon as well as silicon on every heat and by a carefully prepared test piece to gauge the approximate degree of chill. The test piece selected for this purpose was a round plug cast in green sand on end and was 2 in. in diameter and 12 in. long. The plug was allowed to cool at least two hours in the mold before being cooled in water and broken in the middle, and the fractures were designated as grey, low mottled, mottled, high mottled and white. From the same ladle of iron from which the test piece was poured a shot sample was taken for analysis so as to represent the actual iron in the bar as near as possible and the test in all cases was poured from iron taken from the furnace when about half emptied.

It may be well to mention here that the principal disturbing influence on these tests is the fact (proven by experiment) that it is entirely possible to pour a mottled test and a grey test from the same ladle of iron, depending upon the pouring temperature.

In order to study the cause of the variations more systematically a chart was prepared for plotting the analyses with carbon as ordinates and silicon as abscissa. By following up this idea it soon became apparent that the analyses corresponding to the test piece with average chill designated as mottled were arranged along a diagonal line on the chart with analyses corresponding to high and low chill at a more or less definite distance on either side of the line. It so happened about that time that a heat had to be held pretty long in the furnace on account of a break down and it became necessary to doctor it up with 50 per cent ferrosilicon to get the metal into pouring condition. When this heat was out the test piece was examined and found to be just normal or what is designated above as mottled and the analysis corresponding was found to be silicon 1.07 per cent and carbon 2.47 per cent, which served admirably for one

extreme of the chill line as drawn on the chart. In casting about for something to form a point for the other extreme it was found in the shape of a pig of charcoal iron of the same dimensions as the test piece and with the proper degree of chill.

More recently the writer has obtained data for a new high-silicon point in which the analysis was, silicon 1.25, carbon 2.25.

The chart as finally constructed took the shape illustrated in Fig. 1.

As the manganese in all of these heats ranged between 0.25 and 0.35, which is normal for air furnace malleable and as sulphur averaged about 0.06 it will be seen that these elements interfered but little with the results. The phosphorus, of course, was between 0.13 and 0.18 and also had very little influence.

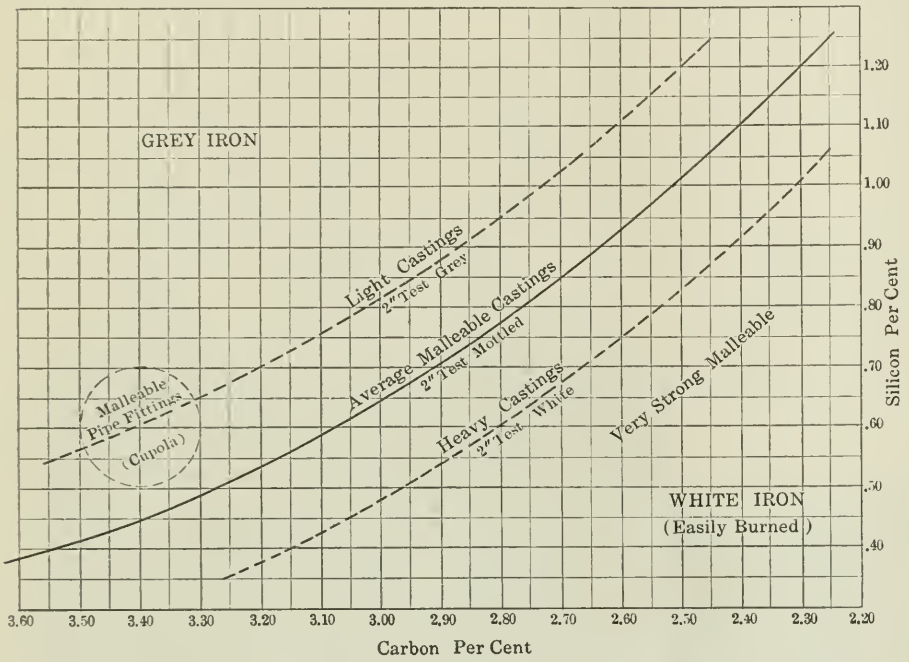

FIG. 1—LINES OF EQUAL NATURAL CHILL AND THEIR APPLICATION TO THE MANUFACTURE OF MALLEABLE CASTINGS

In examining the chart it will be noted that while the line tends to curve somewhat, yet it is sufficiently straight through the usual range of analyses so that for practical purposes we may assume that four (4) points of carbon are equivalent to three (3) points of silicon in the regulation of chill. When the silicon is above 0.70 per cent and below this about two (2) points carbon are equivalent to one (1) point silicon.

The value of this knowledge will be at once apparent to a malleable foundryman as it enables him to substitute large quantities of low-carbon material for his sprue in case of shortage of this material, thus:

It is desired to substitute steel containing silicon 0.10 and carbon 0.30 for 1000 lbs. of sprue containing silicon 0.80 and carbon 2.80.

Equivalent deficiency of silicon in the steel due to low carbon equals $2.80 - .30 \times \frac{3}{4} \times 1000 = 18.7$ lbs.

Silicon deficiency $= .80 - .10 \times 1000 = 7.0$

Total equivalent silicon deficiency $= 25.7$

Therefore, it is necessary to increase the silicon in the mixture by 25.7 lbs. through substituting higher silicon pig iron.

The popular conception of malleable iron accepts the limits of 0.60 to 0.90 in silicon and with a very indefinite idea as to what the carbon content in the hard state should be, but a careful examination of this chart will show that for a given silicon percentage there is a definite carbon percentage which is proper for each class of castings.

In order to prevent cracked work and for other economic reasons the malleable foundryman runs his mixture as nearly grey as he dares, but if he desires to produce a very strong iron the presence of primary graphite in the hard iron must be avoided either by lowering the silicon or the carbon or both.

As to malleable iron produced with the same average chill but with varying analyses it will be found that the high-silicon, low-carbon mixture is more sound and reliable, but it is possibly a little less fluid, while the high-carbon, low-silicon mixture is subject to greater shrinkage and segregation which produce weakness.

The principal consideration for the foundryman is to produce that type of structure which is necessary to obtain malleability upon annealing and the chart shows the proper adjustment of silicon and carbon to bring about the desired results for the different grades of work.

It will be further noted that, of the three factors considered, namely, silicon, carbon and chill, if any two be known the other may be predicted approximately.

Malleable iron produced from the cupola is pretty well confined to the dotted circle shown on the chart, its proximity to grey iron as well as its position in the field of greater shrinkage will account for its weakness, which is not due as popularly supposed to the higher sulphur content. As the carbon is automatically adjusted within this range by melting in the cupola the regulation of chill must be effected by silicon alone. It is not feasible, however, to run a mixture which is lower than 0.50 silicon as the cutting action of the slag produced is very hard on cupola linings. Good malleable castings are being produced along the whole length of the charted lines, but the average foundryman with his limited knowledge of conditions to be met in another foundry cannot see how the other party makes a certain casting with 0.90 silicon while he finds it necessary to make it with 0.60 silicon. It is hoped that the publication of this chart will clarify the matter. The lines here given have been confirmed by plotting hundreds of analyses of mixtures of known chill and normal pouring temperature and the chart has been found a valuable aid in practical work.

The writer desires to acknowledge the inspiration received from an article by Prof. Henry M. Howe written several years ago, in which he urged practical men to take up the study of some data already collected and help interpret its significance. He also wishes to express his appreciation to his late employers, Stanley G. Flagg & Co., of Philadelphia, whose works probably afford better facilities for the study of this subject as applied to malleable castings than any other single plant in this country.

Haskell & Barker Car Co.,
Michigan City, Indiana.

The Arizona Copper Co., Ltd., produced 1201 tons of copper in November, 1914.

Philadelphia Meeting of American Institute of Chemical Engineers

The seventh annual meeting of the American Institute of Chemical Engineers was held in Philadelphia from Dec. 2 to 5.

The opening session of the meeting was held at Hotel Adelphia on December 2 at 10:30 a. m., president M. C. Whitaker of Columbia University presiding. The Institute was welcomed to Philadelphia by Mr. E. C. Cattell, representing Mayor Blankenburg, in an address fairly sparkling with wit and humor. The importance of Philadelphia as a manufacturing center was brought out forcibly by the speaker.

During the business session the result of the ballot for officers was announced. Dr. GEO. D. ROSENGARTEN of the Powers-Weightman-Rosengarten Co. was elected president for the coming year. Prof. J. M. Stillman of Leland Stanford University, Cal., was elected third vice-president. G. W. Thompson, chief chemist of the National Lead Company, and A. C. Langmuir, superintendent of the glycerine refinery of Marx & Rawolle, being first and second vice-presidents. The following officers were also elected: Prof. J. C. Olsen of Cooper Union, New York City, secretary; Dr. F. W. Frerichs of Herf & Frerichs, St. Louis, Mo., treasurer; Prof. A. W. Smith of Case School of Applied Science, Cleveland, O., auditor, and Mr. Geo. P. Adamson, Dr. J. B. F. Herreshoff of the General Chemical Company, and Dr. Samuel P. Sadtler, directors.

The secretary reported 228 members, a considerable gain over the last report. The treasurer reported a very satisfactory financial condition of the Institute, a deficit of long standing having been wiped out.

The Committee on Chemical Engineering Education reported that arrangements were being made with the Carnegie Foundation for the Advancement of Teaching for co-operation in their investigation of the present status of engineering education.

GEORGE D. ROSENGARTEN, PRESIDENT AMERICAN INSTITUTE OF CHEMICAL ENGINEERS

Prof. D. D. JACKSON of Columbia University read a paper on "The Manufacture and Application of the Artificial Zeolites (Permutite) in Water Softening," illustrated with lantern slides and samples of the products. The use of permutite for water softening was explained and a description of the process of manufacture given. Lantern slides giving views of the German as well as a factory in Brooklyn, N. Y., were shown.

Dr. A. S. CUSHMAN and Dr. GEO. W. COGGESHALL of the Institute of Industrial Research, Washington, D. C., presented the results of their investigations and experiments on the commercial extraction of potash from feldspar in a paper entitled "Feldspar as a Possible Source of American Potash." Several hundred tons of potash had been extracted from feldspar. Detailed estimates were given of the cost of a plant capable of handling 300 tons of feldspar daily, showing that potash can be produced from feldspar and sold at a profit. This paper will be published in full in our February issue.

On Wednesday afternoon the plant of the Atlantic Refining Company of the Standard Oil Company at Point Breeze on the Schuylkill River was visited. The method of distillation of the petroleum and especially the fractional condensation of the vapors and the method of control of the temperature of these condensers was examined with great interest.

The plant of the United Gas Improvement Company was also visited. The waste heat boilers were examined with great interest. The retorts are heated by a coke fire, which is fed by the hot coke from the retorts. The hot gases from the combustion of the coke after heating the retorts are carried through the tubes of the nearly vertical steam boilers. The gases enter the tubes at about 1200° F. and leave at about 350°.

On Wednesday evening at the Franklin Institute, Dr. GEO. O. SMITH, Director of the United States Geological Survey, delivered an address on the Distribution of Industrial Opportunities, showing the very widespread distribution of mineral and other natural resources in the United States.

Dr. JOKICHI TAKAMINE then delivered an address on the Chemical Industries of Japan, which include pottery, lacquer, cement, fertilizer, metallurgical and fermentation industries. By means of numerous lantern slides the old Japanese methods as well as modern up-to-date methods of manufacture were shown. A number of slides illustrating Japanese conditions of living were also shown.

On Thursday morning the plant of the Welsbach Works at Gloucester, N. J., was visited. The process of decomposing monazite sand with sulphuric acid, separating the thorium from the other metals and converting it into the nitrate was shown. The entire process of mantle manufacture was inspected, especial interest being shown in the solvent recovery plant where methyl alcohol, acetone and camphor were recovered and separated. The plating department was found to be very complete, nickel, brass and copper plating being shown as well as the production of a great variety of finishing coats and enameling. Brass casting and the manufacture of the metal parts of the lamps were inspected. After the visitors had been photographed a luncheon was served by the company.

During the afternoon a portion of the party visited the yards of the New York Shipbuilding Company, where several battleships are being built. The linoleum works of Farr & Bailey were also visited. The linseed oil was oxidized by blowing air into the oil and also by the older and slower method of exposing the oil to the air in a thin film on large canvas sheets. The oxidized oil was then melted with rosin and gum to produce the linoleum cement. The ground cork was mixed with the cement and coloring matter and applied to the burlap by means of steel rollers. The printing was carried out by means of flat plates, the various colors being applied successively and the finished linoleum suspended in long loops for drying. The manufacture of inlaid linoleums was also shown.

On Thursday evening a subscription dinner was held at Hotel Adelphia with about 50 in attendance. Past President Chas. F. McKenna acted as toastmaster.

Mr. Robert W. Leslie of Philadelphia, delivered a toast to the President of the United States. Mr. Cattell responded for the Mayor and delighted every one with his flow of humor and pathos.

Dr. Geo. D. Rosengarten, the new president, expressed his appreciataion of the honor conferred upon him.

Prof. J. P. Remington spoke of the many valuable services which Dr. Rosengarten had rendered for the advancement of the best interests of Philadelphia.

Prof. M. C. Whitaker urged the great importance

of greater frankness in the discussions of professional problems.

Toasts were also given by Prof. A. W. Smith, Mr. Wm. H. Bower, Dr. H. S. Miner and Prof. Wm. P. Mason.

On Friday morning a resolution was passed favoring San Francisco as the meeting place for the summer meeting of the Institute, the exact date to be fixed early in September by the Committee on Meetings.

A paper on "Hydrometallurgical Apparatus and Its Use in Chemical Engineering" by JOHN V. N. DORR was then read and illustrated by numerous lantern slides. The paper was a very interesting first-hand sketch of what the Dorr classifier, the Dorr thickener and the Dorr agitator have been able to do for the evolution of modern cyanide and general metallurgical practice. The application of the Dorr apparatus to analogous work in various chemical industries suggested itself. An interesting illustration of the increase in scale in modern metallurgical work in a Dorr classifier, 130 ft. in diameter and 6 ft. deep, of the Arizona Copper Company. The first part of this paper is published in full on page 55 of this issue.

Prof. JAMES R. WITHROW and E. H. FRENCH read a paper on the "Hardwoood Distillation Industry," in which they presented the growth of this industry and the gradual evolution of methods and types of apparatus and showed numerous slides of typical installations. The paper, which is published in full elsewhere in this issue (p. 30) was discussed in considerable detail by H. C. Chute and others.

Dr. BERNHARD C. HESSE emphasized in a paper on "Need of Up-to-date Manufacturing Statistics" the great need of recent and reliable statistics of domestic and foreign manufacture and urged the appointment of a Committee of Chemical Engineers to cooperate with similar committees of other technical societies in assisting the United States Department of Commerce in this work and especially calling attention to the needs of the chemical profession in this respect.

Friday afternoon the Commercial Museum was visited, where Dr. Wm. P. Wilson explained the work of the museum. The laboratories of the University of Pennsylvania were then inspected, the members of the Institute being received by Dr. Edgar F. Smith, Provost of the University. Members were very much interested in the old English chemical balance which had been used by Priestley.

Friday evening Mr. G. W. THOMPSON read a paper on "Causes of Paint Defects," in which he showed that many defects such as checking, cracking, peeling, etc., are due to faulty methods of application and not to any inherent defects of the paint materials. He showed that the yellowing of white paint is caused by alkalis and especially by traces of ammonia in the atmosphere. The paper was illustrated by lantern slides.

Mr. H. A. HUSTON of the German Kali Works, explained the methods in use in the German potash mines by means of delightful moving pictures. He also explained the methods in use for refining the crude ore.

Dr. EDWARD GUDEMAN, in a paper on "Aspects of Some Chemical Industries in the United States To-day," showed that it is entirely feasible to manufacture in the United States many of the chemicals needed at present.

On Saturday morning a large delegation visited the chemical department of the Barrett Manufacturing Company at Frankford, Philadelphia, Pa. At this plant the light and middle oils obtained by the distillation of coal tar are used for the preparation of naphthalene and carbolic acid. The oils are first fractioned by distillation and condensation in a column still. The naphthalene is allowed to crystallize out and separated by means of a centrifugal. The crude naphthalene is melted, allowed to crystallize and again separated by means of a centrifugal. It is then treated with sulphuric acid and distilled and the product sublimed. By means of a similar process pure carbolic acid is obtained. Various oils used for disinfecting purposes are also produced as by-products.

About 100 were in attendance at the meeting, which was very successful in every respect.

Dr. John C. Olsen, Cooper Union, New York City, is the secretary of the Institute.

Colorado School of Mines Short Course for Prospectors

To promote the more efficient prospecting of the mineral lands of Colorado, the Colorado School of Mines will establish a short course for prospectors, to be given at Golden, beginning February 8, 1915, and continuing for three weeks.

The work will include both lectures and laboratory studies involving the simple and ready tests for the detection of minerals in the field, as well as a consideration of geological formations favorable for various mineral occurrences.

No fees will be charged for this course other than a nominal charge to cover the cost of supplies used, which should not exceed $3.00.

The course is open to prospectors and others interested in the more intelligent prospecting of our mineral areas.

Electrical Energy Exported from Canada

Of the hydro-electric energy generated along the international boundary in Canada more is exported to the United States than is used in Canada, according to a report issued by the Dominion government. The total production of electrical energy in 1913 by Canadian companies with transmission lines extending into the United States was 1,543,464,097 kw-hrs., of which 772,597,049 kw-hrs. were exported and 770,867,048 kw-hrs. were used in Canada. The totals by companies are shown in the accompanying table:

KILOWATT-HOURS OF HYDRO-ELECTRICAL ENERGY EXPORTED FROM CANADA OR USED IN CANADA

	Exported from Canada	Used in Canada
Canadian Niagara Power Co.	400,214,908	1,1420,020
Ontario Power Co.	282,123,004	412,597,896
Electric Development Co.	42,154,000	191,885,670
Western Canada Power Co.	23,213,891	39,339,239
Ontario & Minnesota Power Co.	21,649,327	868,856

In addition a large amount of hydro-electric energy is generated by Canadian companies in the vicinity of Montreal, Toronto, Quebec and Winnipeg. This is not included in these figures, as none of it is exported.

Resolutions relating to copper as contraband of war were adopted by the American Mining Congress at its recent session at Phoenix, Ariz., appealing to the United States government "to use its great offices to keep open every available market for copper and give full protection to the producers of the metal in the shipment of same in neutral vessels to neutral ports."

An echo of the war is found in the statement that the South African School of Mines has been closed owing to the departure of students to join various units of the defence force. Those who have not been called have been employed by the Consolidated Gold Fields group of mines.

The Rand and the War.—From the *South African Mining Journal* we learn that the president of the Chamber of Mines feels that the position of the mining industry with regard to the war is satisfactory. "Ample supplies of cyanide, zinc and mercury seem assured, and further shipments are now coming forward." Prominent operators express the opinion that the gold industry in South Africa will not suffer.

Handling Iron and Cinder at the Blast Furnace

BY J. E. JOHNSON, JR.

In the early days of the blast furnace it was probably the custom to allow the iron to run out in puddles in front of the furnace and there cool, but soon this crude practice developed into making a runner leading away from the furnace and putting short lateral runners off from one side of it so as to mould the iron into convenient shape for future handling. The runner was rather crudely formed as were the lateral runners, which also were few in number.

The general appearance of the whole arrangement was roughly similar to that of a sow with a litter of suckling pigs, from that comes the name of pig iron, and to this day the runner from which the individual "pigs" are cast is known as the "sow."

In still later times as outputs grew the pigs were not cast directly from the main central runner, but this branched into lateral runners at right angles to its course, and from these, at right angles again and therefore parallel to the main runner, ran the individual pigs. The combination of the branch runner or sow and the pigs which go with it are known as a "bed."

This system of casting the iron persisted as practically the only method of handling it until very recent years. Even at the time of the "Duquesne Revolution" when nearly everything else about the furnace was improved almost past recognition, the handling of the iron was changed only in detail rather than in principle.

Casting in Sand Beds

The runner and beds were until about twenty years ago practically always made up in sand, since sand does not wash in a liquid with a high surface tension like a molten metal, and at the same time is porous enough to permit the gases generated by the action of the intense heat of the iron on the water and organic matter it contains to escape freely. This is a matter of the utmost importance because if such free escape through the sand is not permitted the gases generated will bubble up through the liquid metal when their pressure has risen above that corresponding to the depth of metal upon them, and when this pressure is reached the action is very rapid, because the head decreases as the gas rises, while the volume of the gas simultaneously increases, as it bubbles up through the metal.

The consequence of these ebullitions is that the sand is disturbed when the gas is released, and the hot iron is given access to wetter and fresher sand underneath, with consequent generation of more gases, and its release in turn with a still greater tendency toward violence. This action continues progressively, if it once gets started, until a "boil" results.

These are spectacles of impressive beauty, like magnificent fireworks, for those not concerned in their results, but are frightfully expensive, not only in the loss of iron, but in the difficulty of removing that which remains in the center after the boil is over.

The depth to which one of these boils will dig in a short time is almost beyond belief, and if one occurs close to the front of the furnace so that there is no room to deflect the iron above it, it constitutes one of the worst interruptions that can befall the operation of the furnace.

I have seen a mass almost wholly of iron, but with a little cinder on top, about the shape of a huge strawberry, six feet in height and more in diameter, taken out after a boil of only a few minutes duration, at the end of the iron trough. The difficulty of digging down to the bottom of such a boil and draining the liquid iron from the bottom of it is enormous, and a delay of hours in the operation of the furnace is practically certain to occur as a result of such a catastrophe in this location. For this reason the quality of the sand used in the pig beds, and particularly in the runner, is of vast importance. It must be coarse and open-grained, practically free from clay, and also free from lime, oxide of iron or any similar material which can unite with the silica at the high temperature of the iron and form a slag, and if such a slag be formed it will cause great waste of sand, dirty iron and a tendency to boils by sealing the pores of the sand beneath.

The first great change chronologically from this established method of handling the iron was the introduction of the mixer, of which, however, it will be more convenient to treat later.

Casting in Chills

Next to this came a change forced by the introduction of the basic open hearth process for the manufacture of steel. In this all silica introduced into the open-hearth furnace has to be slagged with lime of something like twice its own amount, which it is very likely to size from the bottom of the furnace, and so cause rapid wear of the latter as well as heavy expense in the consumption of lime.

For this process, therefore, some substitute for sand casting was found to be almost a necessity; this was found in the use of chill molds. These are virtually pig beds of cast iron which replace the ordinary sand beds and are fed from the central sand runner, the same as the original sand bed. These chills are not a modern invention. I have seen one which was made and presumably used at a charcoal furnace before the Civil War, but real need for sandless pig iron did not develop until the early nineties, consequently the chills, which are somewhat troublesome until the details of handling them are learned, never came into general use until then.

Certain irons, particularly hot irons, low in silicon, and made on a very limy furnace have the power of attacking and dissolving cold cast iron and burning to it. Obviously if this action took place to any extent the pigs would burn fast in the chills, and it would be impossible to remove them. To prevent this the molds are grouted with a solution of clay water soon after the removal of the cast from them, their heat then dries the water and leaves a coating of clay all over the chill. This is virtually infusible and serves to protect the chill from the action of the iron unless the latter is of an unusually cutting nature, when it sometimes burns fast to the chill in spite of the clay. Sometimes lime is used in place of clay, but clay is more easily held in suspension in water than lime, and is, therefore, more easy to apply uniformly.

These chills are exposed to enormous stresses. The whole bed of iron is obviously the same size as that of the chill at the instant of solidification, but as the iron cools off the chill absorbs its heat so that one gets hotter and the other colder. In order to get the cast out quickly it is customary to water it down with several hose nozzles as soon as the iron has solidified, and this of course throws still greater stresses upon the chills, but if the molds in the chill which form the pigs are of the proper shape and properly reinforced, they stand up very well under this treatment. It is necessary to have a considerable thickness of metal below the bottom of the pig, six inches is a minimum and eight is considered better. The bars between the pigs are known as the "cores," and including these the average thickness of the chill is from nine to twelve inches. The width of the chill in the direction of the length of the pig is over four feet and its length may be anything dictated by the size of the cast house and local conditions, but beds eighteen or twenty feet long are not uncommon.

A brief calculation will show that these must be very

heavy and in fact they weigh many tons. In some cases the beds are cast in several pieces, two or three, as this reduces the contraction strains and increases their durability, it also makes the individual pieces much easier to handle, although it is more troublesome to keep them in line with one another when made this way, unless longitudinal bolts are provided for holding them together.

Breaking the Iron

Each bed of iron when cast is obviously in the form of a huge comb and to render it merchantable this comb requires to be broken apart, and almost universally in foundry work the individual pigs require to be broken in two, this labor was in earlier days performed exclusively by hand. There are two ways of breaking, hot and cold. The former takes the least labor but is the hottest and the most disagreeable. It consists in catching the iron at the temperature immediately below solidification when it still has very little strength, and breaking the pig from the sow by the use of a crowbar applied under the junction of the two. The men wear clogs with wooden soles an inch thick, kept soaked in water when not in use, which are strapped to their shoes. A good deal of dust arises from the disturbance of the sand, while the radiation from the pig beds is very great in spite of the fact that a thin layer of sand is sprinkled over them, which cuts the heat down very greatly.

In the South where the conditions of atmospheric heat and humidity are relatively bad the custom has arisen of allowing the men to break the iron cold. The beds are watered down as soon as they are cooled below the point where sudden chilling will effect the fracture and appearance of the iron, the men then go on the beds with heavy sledges and crowbars and break the iron from the sow and break the individual pigs in two. This requires more labor and so is more expensive, but the work is more endurable for the men.

When the iron is cast in chills it is watered down and as soon as it has solidified the men work on it in pairs. One takes a short crowbar in each hand and pries up the point of the pig where its contraction has shortened it up so as to leave a gap of about half an inch between it and the chill. This man puts a heavy upward strain on this point with his hand bars, while his partner strikes a hard blow at the junction of the pig and the sow with an extra heavy sledge. This breaks the pig off from the sow and the latter is pried up and broken into two or three pieces by sledging after the pigs are all broken from it.

Casting the iron into chills instead of casting it in sand exercises a profound influence on its structure, particularly with irons low in silicon such as are required for the basic open hearth process and for which chills are used. If the iron be 1 per cent or over in silicon its fracture will be markedly different, when cast in chills, from that produced by casting in sand; it is much closer and finer grained, but the general nature of the iron is not much affected. But when the silicon gets down below 0.8 per cent, particularly if the sulphur be above 0.5 per cent, the iron begins to chill, and if the silicon drops still further it becomes perfectly white, very hard and excessively brittle. This is an advantage for steel making purposes since it has been proven that chilled iron melts more easily than the same iron not chilled, and therefore this facilitates melting down the iron in the open hearth furnace.

But for general foundry work casting in chills has only been introduced very slowly and after much missionary work among foundrymen who have very largely learned to judge the iron by its fracture and general appearance, an iron of open grain with large crystals being in general much superior from the foundryman's point of view to a close-grained iron with small crystals for general work. Therefore casting in chills converted good iron into bad from the foundryman's point of view, and if the silicon was a trifle low converted a really useful iron into one which foundrymen would not consent to use under any circumstances because it was "white."

This condition is gradually wearing away as foundrymen come to use analysis instead of fracture to judge the condition of their iron, but many merchant furnaces supplying the foundry trade still continue, and will for years to come, to cast their iron in sand.

The labor involved in these operations is generally not excessive measured in foot pounds of work performed, but must be done in a relatively short time to permit the cast house to be cleared for the next cast, therefore the men have to do the work under high pressure and under excessively disagreeable conditions owing to the heat and dust.

Pig Breaker

In order to overcome these hindrances to continuous and inexpensive operation the Duquesne furnaces were provided with chill beds, but they were also provided

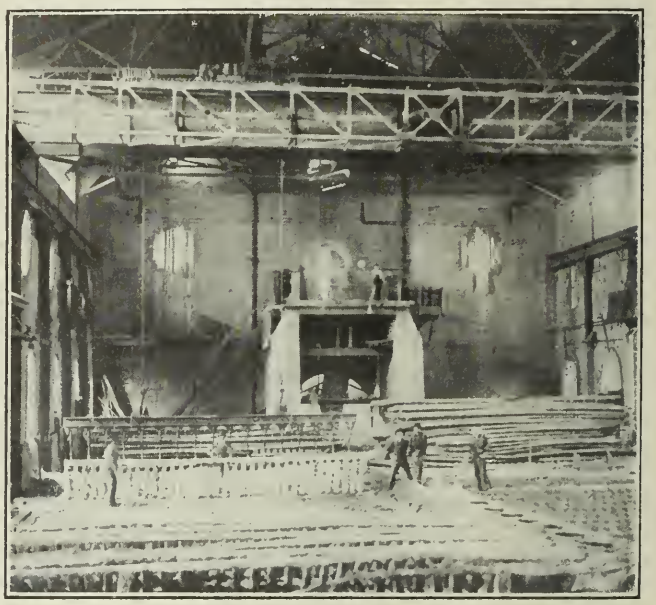

FIG. 1—INTERIOR OF CAST HOUSE WITH PILE OF PIG BEDS. CRANE LIFTING ONE PIG BED OUT OF SAND

with a crane in the cast house and the individual pigs were made vastly larger, both of heavier cross section and much longer than the ordinary pig, and were picked up by the crane which carried them to what was probably the first mechanical pig breaker. There they were laid down upon a table of rollers which fed them up to a hydraulic plunger working up and down which broke them into short sections.

Since that time the introduction of the crane in the cast house has become more general and should be universal. It is not only an enormous saving of labor in handling the iron, as I shall presently show, but is a convenience of incalculable value in times of breakouts, boils, putting in and taking out iron troughs, and assisting in the operation generally.

Since the time of the Duquesne Revolution the pig breaker has been much more highly developed, and in modern plants where pig beds are still used the handling of the iron is reduced to a mechanical operation.

The Brown Hoisting Machinery Company of Cleveland have developed the pig breaker in most common use, and through their courtesy I am able to show in Figs. 1, 2, 3, 4 and 5 the whole operation of handling the iron. In Fig. 1 there will be seen suspended from

the crane an I-beam carrying a number of heavy steel hooks. These hooks are lowered down over the bed and a couple of them are hooked under the sow and raise it onto blocks as shown in Fig. 2, in which position a fresh hold is taken of it with practically all the hooks engaged, the whole comb constituting a bed of two or three tons weight, may either be taken directly to the breaker in the rear or piled up as shown to the left of the breaker at the rear of the cast house. This is of particular convenience in case it is desired to have the analysis of the whole cast before breaking the iron and delivering it into the cars.

Fig. 2 shows the pig bed hanging from the hooks with its end entering the jaws of the breaker. It will be noted that the breaker is set at a high level, and in the center between the two piers on which it rests may be seen a chute leading out of the arch doorway at the rear. Into this chute the pigs drop as they are broken and slide into the car which takes them to their destination. The iron therefore is practically never touched by hand in any way until it comes to be unloaded at its destination, and while that is no part of our present concern,

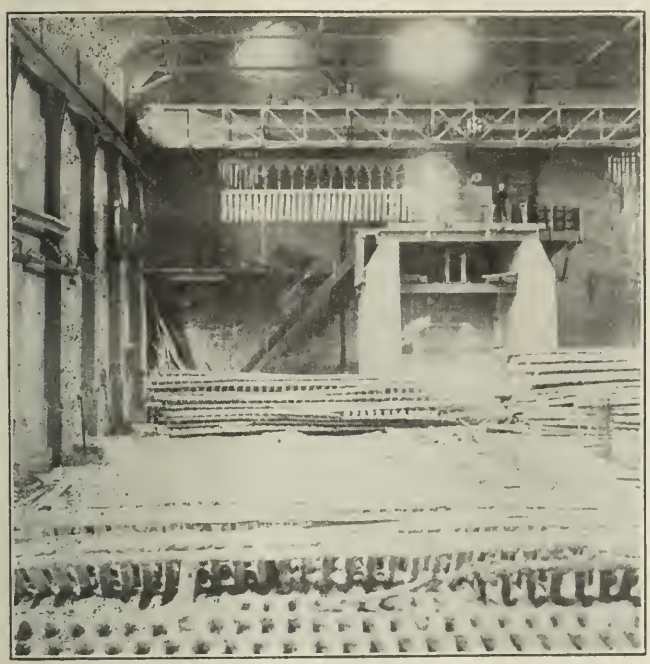

FIG. 2—INTERIOR OF CAST HOUSE WITH PILE OF PIG BEDS, ONE HANGING FROM CRANE

it is not amiss to say that that operation is now very generally carried on by huge magnets operated by cranes, so that even there no hand labor is required.

Figs. 3, 4 and 5 show the pig breaker itself. The vertical column at the left carries two horizontal plungers, one above the other, operated by hydraulic pressure. The column at the right acts merely as an anvil. In operation the comb is fed between the jaws by the crane; the first plunger is driven out against the top of the pig just where it joins the sow, and forces this over firmly against the anvil. The lower plunger is then forced out against the projecting bottom end of the pig, which it breaks off across the horizontal fulcrum seen about midway of the height of the anvil. This breaks the pig in two. The sow being supported by its top edge, with the bottom edge unsupported, while the end of the remaining portion of the pig is supported on the fulcrum, more pressure is then thrown on the top plunger, which is opposite the unsupported bottom edge, and this additional pressure breaks the pig loose from the sow, the sow is then broken into suitable lengths by proper manipulation of the position of the comb and of the pig breaker itself.

The hole in the floor just to the right of the operator delivers the pig into the top of the chute shown in Fig. 2. There is one of these on each side of the machine, so that no matter on which side the pig falls it reaches the same destination.

A pig machine has also been brought out by Mr.

FIG. 3—SIDE VIEW OF PIG BREAKER

James B. Ladd of Philadelphia, but the principle of this machine, while somewhat different from that of the Brown, is not so radically different as to require separate illustration.

The amount of labor saved by the introduction of this equipment is enormous. When it is realized that 500 tons is considered the normal output of a standard size furnace in the Lake Ore district, and that under the old regime this would have required to be broken by hand, then carried piece by piece and thrown onto trucks, by them carried from the cast house to the railroad car, and then thrown from the trucks to the railroad car, it will be seen that the labor involved was

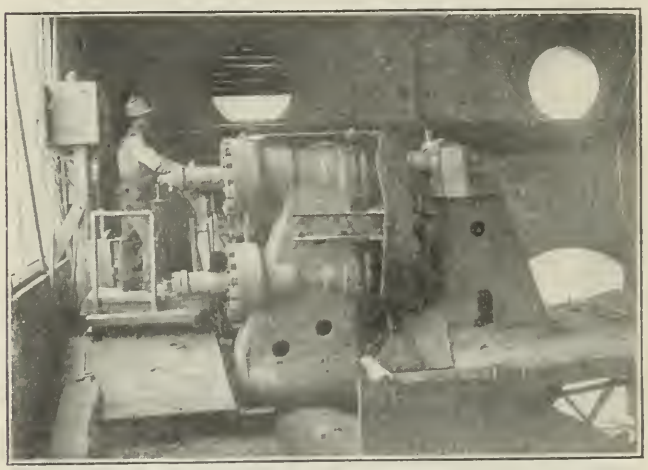

FIG. 4—PIG BREAKER, SHOWING HYDRAULIC CYLINDER AND ANVIL

tremendous and of the heaviest and most undesirable kind. Such labor is increasingly difficult to secure, and to handle, and the introduction of methods of handling pig iron by machinery is almost a necessity where it must continue to be cast in sand.

Molding Up Sand Beds

The beds were formerly molded exclusively by hand and still are in many cases. The sand is leveled off in the cast house floor, there is a pattern for the sow

and one for each pig, which are set down on the level surface thus prepared, the sand removed from the bed to level it is thrown back between the pigs and tramped to place to pack it, then struck off the top of the pig patterns, which are made with a considerable taper, these are then drawn by hand and thrown to the place for the next bed below, followed by the sow pattern.

This is probably the most laborious of any operation of considerable degree left around the blast furnace, and no means have been found as yet to reduce it to a very great extent, although where there is a crane in the cast house the pattern for the whole bed is made up in

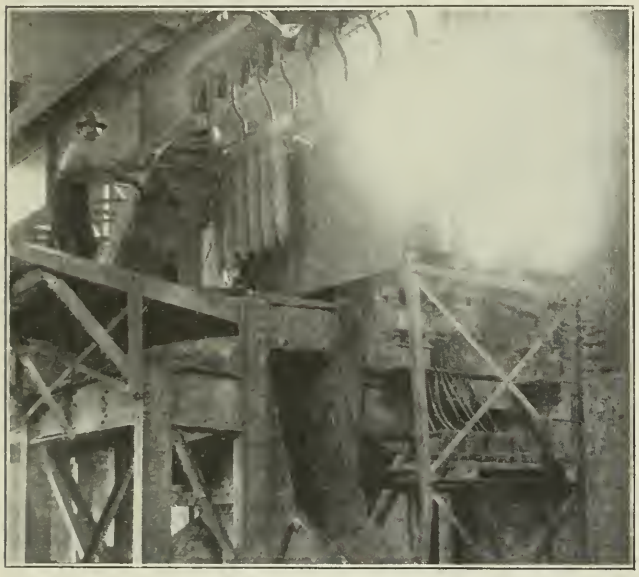

FIG. 5—PART OF PIG BED OR COMB IN JAW OF PIG BREAKER

one piece and handled by the crane; this saves a certain amount of manual labor, but so small a proportion of the total that the practice has been abandoned for the use of the old single patterns in some cases.

Various attempts have been made to reduce this labor but the sand has to be cut up with shovels after each cast has been watered down, not only in order to set in the pigs, but also because it is too much compacted by the wetting to provide the necessary free vent for the gases. This, with the necessity of having the beds nearly level with just enough fall to the sows and the pigs to cause the iron to run into them without overrunning the far ends, has made conditions too difficult to be met by machinery sufficiently simple and robust to perform the service in other particulars.

It seems not improbable now that the increasing use of the casting machine will eliminate sand casting entirely before mechanical methods are developed for molding the pig beds.

Handling Liquid Pig Iron

In the early days of the Bessemer Process, the first applied to the manufacture of steel on a great scale, it was customary to cast the iron at the blast furnace as described, take it to the steel works, melt it down into cupolas and then take it to the converters for conversion into steel. This was done so that an opportunity might be provided to analyze the iron and to make the mixture in the cupola suitable for use in the converters. This practice involved an enormous waste in two ways, first the labor of casting the iron into pigs as described above, and the disposal of the pigs; second, the labor and fuel required for remelting this in the cupola. This was accompanied by a very objectionable increase in sulphur from the coke used in remelting.

Many metallurgists sought to eliminate this double loss by using the metal direct, but furnace practice was not as regular and uniform in that day as it is now, and there was no certainty that the iron produced at one cast would be suitable for the converters because the last cast had been, and if the variation in composition were great the converter practice was completely upset.

The late Captain W. R. Jones, of the Edgar Thompson Works, solved the difficulty by the invention of the "mixer," a huge steel vessel lined with fire brick, mounted on trunnions and tipped back and forth for pouring by a hydraulic cylinder. The first of these had a capacity of 150 or 200 tons of iron, but later ones have capacities up to 600 and 800 tons.

All the iron from all the furnaces is poured into this mixer and that for all the converters is drawn from it. This provides a "cushion" to absorb the fluctuations in the quality of the metal and secures gradual variations of the metal delivered to the converter, which enables the converting mill to adapt itself to these changes without difficulty, while of course the mere fact of mixing the output of three or four furnaces necessarily reduces the average variation at least to one-third or one-fourth of that for any individual furnace, and generally much more.

Thus the mixer exercises two good influences. It greatly reduces the absolute size of the variations, and it makes them gradual instead of sudden. This improvement permitted the use of direct metal at the steel works, and practically all modern plants of combined blast furnaces and steel works operate on this system. Where steel is made by the basic open hearth process as well as by the Bessemer, a separate mixer is used for this iron, and the same advantages are secured in that practice.

The use of "hot metal," as it is universally called, for the steel works involved the necessity of having ladle cars to transport it from the blast furnace to the mixer and thence to steel works. These started out

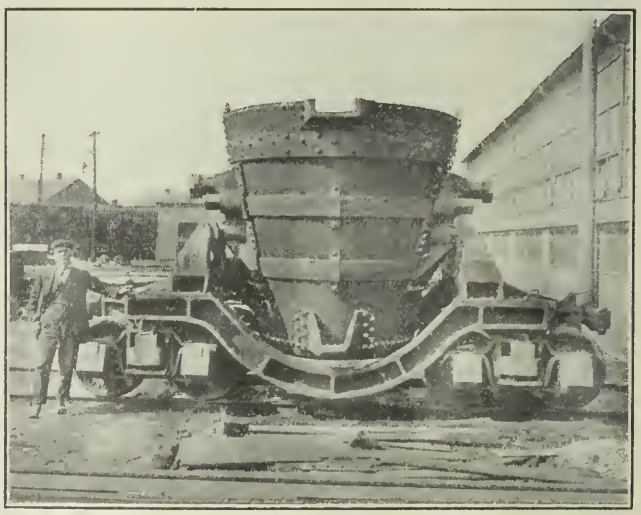

FIG. 6—POLLOCK HOT-METAL CAR

quite small, ten or fifteen tons capacity, but have gradually grown with the increased use of hot metal until 45, 50 and 60-ton ladles are now considered standard.

A ladle capable of carrying this amount of molten iron sometimes for distances of several miles, with entire safety from breakage of the apparatus or liability to accidental tipping, and yet capable of being easily poured where desired, is an apparatus of no mean proportions.

Such a ladle built by the William B. Pollock Company

is shown by Fig. 6. It will be noticed that this ladle is provided with five trunnions, two pairs below and a single one above on each side. It is also provided with a spout on each side and with a pocket for a hook at the bottom immediately under the spout to provide a convenient hold for the tilting mechanism. The single trunnions above are used in carrying the ladle on cranes; the two lower sets are used for pouring from the frame of the ladle car itself. The ladle revolves during the early part of the tilting movement around the forward one of the bottom pair of trunnions, but if it continued to revolve about this until empty its spout would be very low, necessitating a heavy drop for the metal poured at first in order to make room for the spout in its low position.

The purpose of the upper pair of trunnions with the corresponding jaws on the ladle truck shown beneath them is to prevent this low drop of the ladle spout, and it is obvious that when these upper trunnions reach a seat in the corresponding jaws on the truck the ladle revolves around them, the lower pair leaving their seats. This obviously throws the spout up much higher at the conclusion of the pouring operation. By this means the drop from the spout of the ladle is reduced several feet over what it formerly was, which is an advantage wherever it is used, but particularly in connection with casting machines to be described presently, of which the receiving end with the old style ladle had to be placed below the track, but with the style here shown,

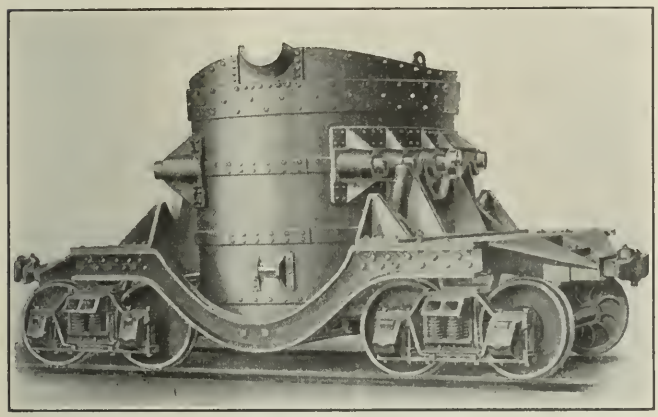

FIG. 7—TREADWELL HOT-METAL CAR

on account of the high position of the spout at the end of the pour, these machines can be raised above the track with the result of making them much more accessible and less expensive to install.

A hot metal ladle built by the Treadwell Engineering Company is shown by Fig. 7.

Casting Machines

The increase of furnace outputs during the nineties, of which I have spoken, required very large cast houses to take care of the iron, and the labor involved in breaking and carrying out these huge quantities of iron by hand was, as I have already explained, frightful. The entire plant depended upon iron carriers, since the furnace could not be operated unless the iron were carried out not *some* time but within a very limited period, so as to permit the beds to be made ready for the next cast. These conditions had the result of making this class of labor extremely hard to handle.

Conditions in this respect were, in one way, made worse by the growing use of hot metal at the steel plants, because it was necessary to have the iron carriers for Sundays and for emergencies when the steel works could not take the iron, while these men were not needed the rest of the time. This brought a demand for a mechanical means of taking care of the iron from the furnace. Casting machines had been in use at a much earlier period for copper, lead, etc., on a small scale, and under rather easy conditions, owing to the fact that the temperatures of those metals are far below the melting point of iron, so that iron molds could be used without great difficulty. But the case was quite otherwise with the blast furnace; the only material of

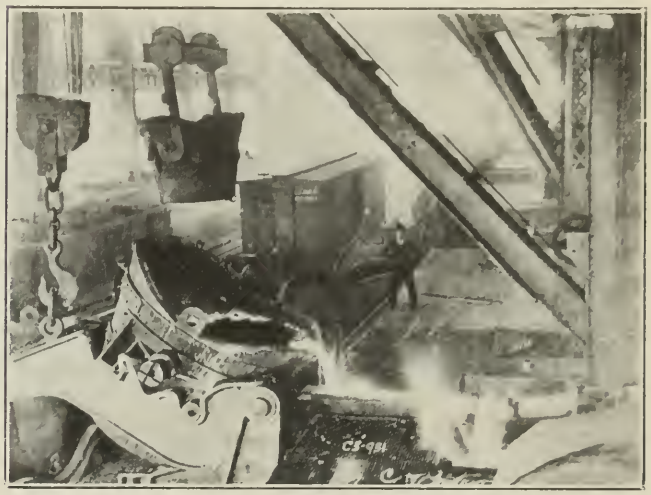

FIG. 8—HOT-METAL LADLE IN POURING CHAIN, POURING INTO BRANCHING TROUGH FILLING MOLDS

construction available was iron or steel, and the iron cast into either of these was likely to burn fast to them if they were not thoroughly protected, while if the metal was poured into them while wet violent explosions would result.

Various engineers attacked this problem, but the credit for the first successful solution belongs to E. A. Uehling, who designed a machine consisting of two endless chains in tandem. The first carries molds for the pigs into which the iron is cast, it is chilled by passing under a heavy spray of water on its course, then discharges at the terminal sheave onto the second chain, a conveyor of slats running for some distance under water, which cools the iron down to a temperature low enough to do no harm, this conveyor in turn discharg-

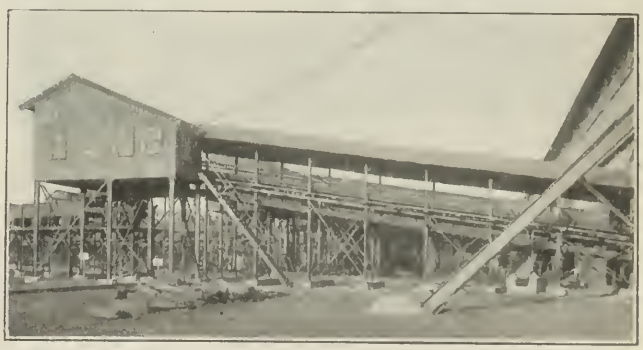

FIG. 9—FIRST OR CASTING CHAIN OF GROUP OF UEHLING MACHINES

ing onto the railroad cars which take the iron to its final destination.

Through the courtesy of the Heyl & Paterson Company I am able to show drawings, and an excellent set of photographs, of one of the largest installments of these machines ever built. Fig. 8 shows the ladle in a tipping chair which is elevated by the jib crane shown at the right and pours into a trough at right angles to the track, which branches both ways at its far end, each

branch pouring onto a separate strand of the pig machine.

Fig. 9 shows a general view of the ascending chain of the machine with the returning buckets on the under side.

Fig. 10 shows clearly a general view of the machines, the head houses where the casting chains discharge onto the cooling conveyors, the terminal houses from which the latter discharge into the cars, and the excellent ladder arrangement of tracks for serving the machines without the necessity of switching the cars under all of them to reach any desired car.

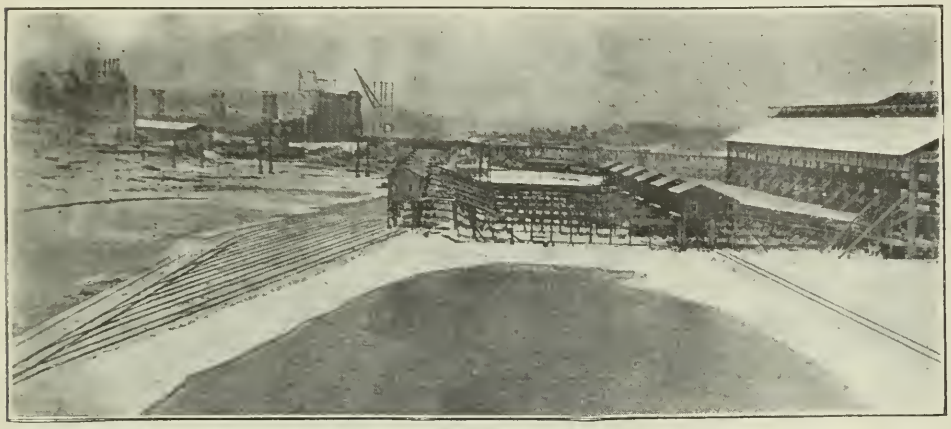

FIG. 10—GROUP OF UEHLING TYPE MACHINES

A view of the cooling conveyors with their water trough and the return side of the chain below is shown in Fig. 11.

The difficulty of having the metal burn onto the molds is obviated by having a jet of lime water from a tank underneath the return chain thoroughly sprayed up into the buckets as they pass over it on their return trip. The heat remaining in the mold causes the lime water to dry on it in a heavy white film, which of course is extremely refractory and prevents the contact of metal to metal, without which burning fast does not occur.

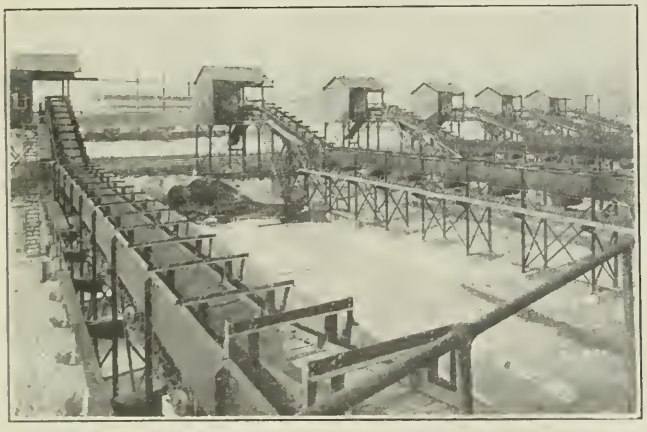

FIG. 11—COOLING CONVEYORS FOR UEHLING TYPE OF MACHINE. WATER TROUGHS EMPTY

Another type of machine was brought out about the same time in which the functions of both chains are merged into one. This was the design of the Heyl & Paterson Company, who now build both the Uehling type of apparatus and their own.

In this apparatus one chain performs both functions. The metal is cast into it at one end, it then passes down a slight grade into a long tank standing full of water where the iron is thoroughly cooled, rises out of this tank at a sharp elevation and is discharged over the end sheaves directly into railroad cars.

A photograph of an installation of this type is shown at Fig. 12, also by the courtesy of the Heyl & Paterson Company. Unfortunately the machine was empty at the time the picture was taken, but the molds show so clearly, also the way in which they pass under the water and out again and the overflow for keeping the water at the proper level that their action is perfectly obvious. A photograph of the same apparatus before the water was turned into the tank is shown in Fig. 13. The molds used in this conveyor are of steel, formed in a hydraulic press out of a piece of plate. They are subjected to terrific strains with the hot metal on one side of them and the cold water on the other, and after a certain amount of this service they lose their shape but can be repressed and restored to useful condition several times before they break from this treatment.

In some cases cast iron molds are used instead of steel. These of course fail by cracking and not by bending and are not capable of any further use after such failure. On the other hand they can be melted up and recast direct from the furnace in the floor of the cast house with very small expense, whereas when the steel molds once fail the loss is greater.

Both styles of molds have their advocates and both continue to be used after a number of years experience, so that the question of whether it pays better to use one kind or the other is probably very largely a local question.

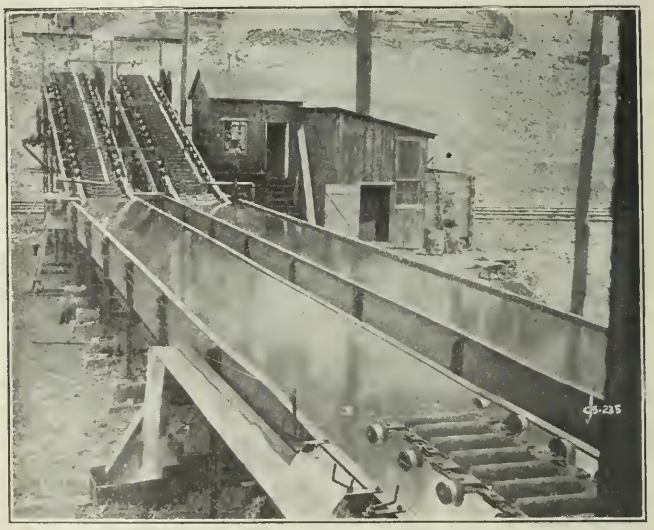

FIG. 12—HEYL & PATERSON TYPE OF CASTING MACHINE, STEEL MOLD SINGLE CHAIN, TROUGH FILLED WITH WATER

The merchant blast furnace isolated from steel wo ks will probably prefer the cast iron molds which it can produce from its own metal with a small amount of labor, while the steel works making steel plate and having available machinery for pressing the molds may find it cheaper to use the steel.

The introduction of casting machines of one type or

the other has become practically universal at blast furnaces directly connected with steel works, and even at many merchant furnaces. The huge cast house which was one of the prominent features of the blast furnace of former times has disappeared at such plants and nothing is left of it except a building large enough to cover the troughs in which the iron is run to the spouts above the ladles and to serve as a protection

FIG. 13—HEYL & PATTERSON TYPE OF CASTING MACHINE, STEEL MOLD, SINGLE CHAIN

against the weather around the base of the furnace itself.

Iron Troughs and Skimmers

A few feet of iron runner next the tapping hole has been used for many years, for the reason that if properly grouted and dried it is reasonably free from the danger of having the iron burn fast to it on one hand, and on the other entirely prevents unexpected moisture or other causes from producing a boil close to the tapping hole, because while a violent explosion is caused by molten iron running onto even the smallest wet spot on anything made of iron, it is prevented by the iron from burrowing deeper after each explosion, as it does when a boil starts in the sand.

A bad boil immediately at the tapping hole would prevent the shutting of the latter, and would put the furnace out of commission for an almost indefinite time and would constitute a catastrophe, therefore the iron trough is used to prevent this at all hazards.

Up to within a few years the runners from this point on were entirely of sand and the necessary arrangements for skimming the cinder from the iron were also built up of sand. The cinder has a specific gravity only about one-fourth to one-third that of the iron, and while the two come out of the tapping hole together during the latter part of the cast the cinder immediately rises to the surface and can be skimmed off without difficulty. To accomplish this the portion of the runner next to the iron trough is made very large relative to the portion below this point and a dam of sand some five or six inches high is put into the bottom of it four to eight feet from the iron trough; just above or in front of this is set a skimmer, formerly a thick plate of iron cast in open sand in the floor of the cast house, and guided by two pairs of pins driven into the sand of the runner on each side of it. When the cinder begins to show on the iron this skimmer is driven down with a hammer until its edge projects below the surface of the metal sufficiently to prevent the head of cinder floating on the iron from pushing under it, the cinder then rises and flows over a lateral dam, a low place in the side of the sand trough, and is led from there to its point of ultimate disposition.

With large and rapid streams of iron which were the consequence of the growing outputs of the nineties, this operation became more difficult and less certain. Either cinder was allowed to get down onto the iron, which created a fearful nuisance as the cinder broke off when the iron was cold and fouled the pig beds, or the iron itself would be forced out over the cinder dam and wasted. Moreover there was left in the basin formed by the iron and cinder dams at the end of the cast a considerable volume of iron with a heavy layer of cinder on top of it. To direct this iron to its proper place and keep the cinder from following it was by no means an easy matter, and much iron was likely to be lost in the cinder without the most careful practice.

In order to overcome these difficulties Mr. Michael Killeen at the Edgar Thompson works devised the Killeen skimmer. This consists of an additional section of iron trough linked to the section next the furnace. It has cast with it the cinder and iron dams, a slot in which to set the skimmer (preferably made of firebrick in an iron frame to prevent its cutting away during the cast, as the old iron skimmers did), and a supplementary lateral outlet extending clear to the bottom of the trough and closed by an iron gate with a loop in the top. Before cast this gate is set to place and the point between it and the body of the skimmer trough well protected with sand and grout. With this arrangement the skimmer can project far enough below the surface of the iron to prevent the possibility of cinder getting down the iron runner, while at the same time the cinder dam can be raised so high as to prevent the iron from rising over it and running to waste. The considerable volume of iron remaining in the trough at the end of the cast is released by withdrawing the supplementary lateral gate and allowing the iron to run into a special runner which takes it either into a ladle or to a special bed set below the level of the other beds as may be preferred. The cinder is prevented from following it by a hand gate dropped when the iron is all discharged and before much of the cinder can follow. This not

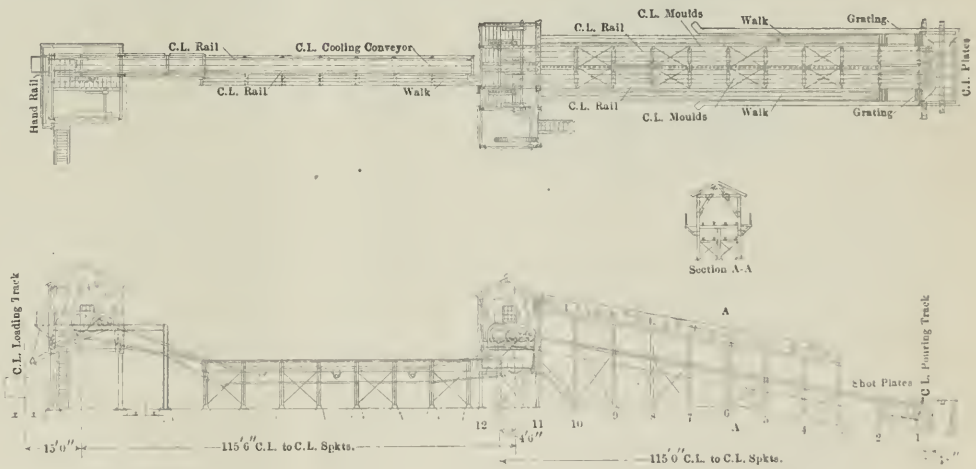

FIG. 14—GENERAL ARRANGEMENT OF UEHLING CASTING MACHINE

only prevents the iron from being wasted and the cinder from getting down the iron runner, but also drains the iron trough effectively to the bottom so that easy access is thereby afforded to the tapping hole in order to stop it.

Other forms of skimmers have since been brought out, but are only variations of the general principle of the Killeen design.

Following the introduction of the iron skimming trough iron runners were substituted for the sand runner all over the cast house. These are provided with grooves into which gates are set to cut off the flow of the metal, and are grouted after each cast with a mixture of sand and clay kept hot by a steam coil, the gate grooves being filled up flush with this mixture. With good practice only a very light skull of iron is left in these iron runners when the cast is over, and the runner requires only a new coating of sand and grout to make it ready for use again.

On account of its smoothness and uniformly sloping bottom the iron runner drains itself better than the sand runner, which prevents the formation of any but light scrap; moreover, with the iron runner it is possible to raise a gate which has once been set and allow iron to flow again down a section of trough from which it had been cut off, which it is never safe to do with sand runners because the withdrawal of the gate from the sand is extremely likely to cast a boil. These advantages have resulted in the universal introduction of iron runners where the iron is run direct to the ladles and not cast in sand beds.

(*To be concluded in February Issue.*)

Chemistry and Lighting

The New York Section of the American Electrochemical Society opened the season by a session at the Chemists' Club on the evening of November 10, devoted to a symposium of papers on contributions of chemistry to illuminating engineering. The meeting was held in co-operation with the American Illuminating Engineering Society and the American Gas Institute. The chairman of the New York Section of the American Electrochemical Society, Dr. Colin G. Fink, of the Edison Lamp Works of the General Electric Company at Harrison, N. J., presided.

COLIN G. FINK, CHAIRMAN NEW YORK SECTION AMERICAN ELECTROCHEMICAL SOCIETY

Introductory Remarks of Chairman

Dr. **Colin G. Fink,** in his introductory remarks, said that in the development of new and better forms of illumination chemistry has played a most important part. "For many decades the element carbon has been the basis of the best illuminants, whereas to-day we find investigations proceeding in three distinct lines: rare earths, rare metals, and rare gases. Professor Nernst and Baron Auer von Welsbach are among the most noted exponents of the rare earth investigations which have led to the Nernst glower and the modern incandescent gas mantle. Few of us realize that the modern electric arcs embody chemical problems which are only partially solved.

"And yet the very best and most efficient forms of lighting of to-day realize but 6 per cent of the energy, 94 per cent being lost as heat. The very best minds in America and abroad are striving and seeking to produce a light as economical as that of the firefly, whose little 'lamp' 'burns' at an efficiency of 98 per cent."

Chemistry of the Incandescent Gas Mantle

Dr. **H. S. Miner,** chief chemist of the Welsbach Light Co., Gloucester City, N. J., presented the following paper:

In responding to the invitation to tell you some of the new developments in the chemistry of the incandescent gas mantle, I very much fear that my hearers will be doomed to disappointment if I am expected to describe some startling change that has taken place in that industry. Since the wonderful and spectacular invention of the brilliant Austrian chemist, Dr. Karl Auer von Welsbach, who about thirty years ago produced the incandescent gas mantle which in all justice bears his name, the growth of the industry has been marked by steady improvements rather than revolutionary changes, unless indeed we are to include that radical change in the composition of the mantle body which Dr. Auer himself made, when in the early nineties he substituted the thorium-cerium mixture for the more complex lanthanum-zirconium-cerium mantle which had comprised his first commercial mantle body. This was indeed a radical improvement, and it marked the beginning of the general adoption of the incandescent gas mantle.

I have said that the days of *radical* developments seem to be in the past, and yet I never cease to wonder at the phenomenon of the change or petrifaction of the vegetable or organic fiber, reproducing the cellulose fibre in mineral form under the influence of the Bunsen flame and giving the light-producing body with which we are familiar. And although we hear the fragility of the mantle frequently alluded to, yet when I watch its formation in this manner, which seems to be essential to its light-giving efficiency, the strength and resiliency of the mantle is a "nine days' wonder" to me.

This change in the composition of the Welsbach mantle when the mixture of 99 parts of thoria and 1 part of ceria was substituted for the earlier mixture, has ever been to my mind an invention of the highest type, involving as it did the purification of rare earth materials beyond the limits of previous knowledge, and then the development of commercial processes for the

production of these rare earths in the highest state of purity.

Notwithstanding the extravagant claims made by many *pseudo* inventors, the thorium-cerium mixture still holds as the essential composition of all Welsbach mantles, and this, and this alone, is the basis of the light-giving qualities of the incandescent gas mantle; although the last quarter of a century has brought us much enlightenment upon the field of rare-earth chemistry, no satisfactory substitute has been found for this early invention of Dr. Auer's. An intimate knowledge of this industry from the very days of its infancy leaves me with an ever-increasing respect for the work of the pioneer, Dr. Auer.

In justice to the faithful and meritorious work of the many rare-earth chemists throughout the world, I would say that their work has resulted in certain changes and improvements in the mantle and burner which have decreased its cost and increased its efficiency and durability. Some of these points I will endeavor to touch upon.

In the early days a purified cotton fabric was saturated with the thorium-cerium mixture made of materials of as high a state of purity as possible. The purity of the cellulose was found to be absolutely essential, and the well-known bleaching and washing processes were carried beyond the point previously thought to be necessary, and a cotton carrying less mineral substance than the best absorbent cotton was soon produced. Realizing the deleterious influence of foreign substances, such as silica, lime, magnesia, alumina, phosphoric acid, etc., it was recognized that it was just as harmful to have these elements brought to the mantle from the vegetable fibre as from the rare-earth mixture.

It was early recognized that the length of the fiber or staple of the mantle fabric had much to do with its physical strength and its durability. Long staple cottons were used exclusively in the best grade of goods, and the longer fibered ramie or China grass was looked upon with favor when it was first introduced, but it was not used with any success by mantle manufacturers until it had been successfully de-gummed, bleached and washed. The accomplishment of this complex and difficult problem resulted in the adoption of ramie as a mantle fiber first in Germany and then in other countries. The adoption of ramie fiber made possible the mantle of the inverted or pendant type, which has since been so generally adopted.

Although the staple of the fiber had been increased in length from 1½ or 1¾ inches to 5 or 6 inches by the substitution of ramie for Sea Island cotton, and that with certain advantages, especially in inverted mantles, yet the ideal had not been reached, and it remained for the artificial silk or artificial cellulose fibers to supply that ideal. The delay in the development of the artificial silk industry caused a delay in the adoption of artificial fibers as a mantle-making body, but its many striking qualities of strength, elasticity and maintained candle-power have caused a persistence of effort that now had its reward in the arti-fiber mantle.

In the early days the only digressions from the ideal composition of 99 per cent ThO_2 to 1 per cent CeO_2 were slight variations in these figures within narrow ranges to produce lights with varying degrees of whiteness, an increase or decrease of ceria increasing or decreasing the yellow color of the light produced. The coming of ramie fiber and the inverted type of mantle made the introduction of small percentages of hardening materials essential, and beryllium oxide was found to be an ideal substance for this purpose.

The change of fiber and of the type of the mantles as indicated has caused a complete revolution in the processes of manufacture, and notwithstanding the experience already gained, each one of these changes has called forth a line of research that had made persistent work over a period of years essential before the problem could be considered solved. This is especially true of the arti-fiber mantles, and the changes in manufacturing processes have extended to the collodion or lacquer used to strengthen the mantle for transportation, for the collodion used on the cotton or ramie mantles was found to be entirely unsuited for arti-fiber mantles.

The problem of primary importance for the chemical engineer, as related to this industry, has ever been the manufacture of thorium nitrate, and many changes in the commercial production of this substance have, of course, been effected during the score of years just past. Monazite sand has always been, and still is, the only commercial ore from which thoria could be obtained, and contains from 5 to 6 per cent ThO_2; although small deposits of thorite and thorianite with a thoria content of 50 per cent and 75 per cent respectively have served to keep alive within us an appreciation of, and longing for, a more ideal ore as a source of supply. The high price of monazite—this very low-grade ore from a thoria standpoint, with nearly 95 per cent waste—has thrown upon the thoria content, while still locked up in this phosphate rock, a heavy burden of expense and has made necessary the production of high yields and low costs of operation to keep the cost of thorium salts low enough to make them commercially available.

The first processes used in factory practice were naturally but enlargements of the well-known laboratory methods of analysis, while from this beginning have developed modification after modification, substituting cheaper and cheaper reagents and methods of manipulation until the commercial processes of to-day hardly bear even a "family resemblance" to the first process employed. These modifications are, of course, still continuing, and are made imperative by the fluctuation in price either of the ore, of some reagent, or of the price of labor. But although there be variations in processes, there must be one unvarying standard ever before the chemist in charge and all of his associates, and that is the absolute purity of the product. Pure thoria is vitally essential, and I am gratified to be able to say for the thoria manufacturers of the world that their product is of very high grade and is better now, notwithstanding the cheapening and shortening of processes, than it was in the beginning, although even then it was sincerely labeled "C. P."

There are various means, both chemical and physical of checking and determining the purity of the product, but in the light of experience the most satisfactory method for both accuracy and rapidity is the manufacture of mantles from the thoria as it progresses in purity. The color of the mantle body, the color of the light produced, the presence or absence of shrinkage, the brittleness or flexibility of the mantle give to the experienced manufacturer a more satisfactory indication of the purity of the product than do the chemical analyses, which are of necessity long and tedious.

The other essential material which must always accompany thoria is ceria, and although it is used in only about one one-hundredth the quantity as thoria, yet its chemistry is just as important and its purity just as essential. I am glad to say that this product is even purer than when Dr. Auer first used it even in larger proportions in his lathanum-zirconium-cerium mantle. The oxide of cerium then obtained was of a reddish-brown tint, while that now manufactured is of a light yellow color, the former product having been slightly contaminated with neodymium, the last traces of which were difficult to remove.

By way of variety, and in order to add zest to the

work of the mantle chemist, he has also to manufacture beryllium, zirconium and neodymium, each of which he uses in a limited way, and none of these substances are really easy to produce.

Radio-chemistry has recently thrown the thoria manufacturer into the "lime-light" because of a radio-active product three hundred times stronger than radium, which occurs in and is produced from the thorium which he manufactures. I refer especially to meso-thorium, which a suffering and stricken humanity has implored the thoria manufacturers of the world to save for them, and which these manufacturers are now unitedly conserving as a substitute at least for radium.

With the possible exception of the meso-thorium just alluded to, every problem we have mentioned has a bearing upon the characteristics and qualities of some or all types of incandescent gas mantles. There is another and no less important problem, however, that should be alluded to, and that is the protective coating that must be applied to a finished mantle to strengthen it temporarily for transportation. In the early part of 1888 we were dipping the finished mantle in an alcoholic solution of shellac, made slightly flexible upon drying by the addition of a little castor oil. Some essayed to strengthen the mantle by the use of paraffine, and I have in my collection of curios a mantle imbedded in a cake of paraffine, which was to be removed by the melting away of the paraffine wax.

The invention of solutions of nitro-cellulose or soluble cotton opened up a new field of research, and the knowledge gained of the many various forms of nitro-cellulose and the numerous solvents therefor, together with the knowledge and control of such characteristics as viscosity, hydroscopic effects, etc., have made it now possible to prepare collodion solutions of almost ideal qualities for mantle purposes.

And what are these ideals? A collodion must be of the proper viscosity for mantles to be dipped in and withdrawn from it without rupture or strain; it must dry quickly with a film stiff enough for the mantle to be handled with safety, and yet strong and elastic enough to resist handling and shock; it must burn off slowly enough to prevent the mantle from becoming annealed or softened, and yet it must not leave the mantle body sticking to the cap of the burner. A collodion which answers these ideal characteristics is now realized in a nitrocellulose solution in a mixture of solvents with camphor made flexible chiefly by the use of castor oil.

I said in the beginning that the type of spectacular developments in the incandescent mantle industry were apparently over. At the close of this very general review I am, however, strongly tempted to modify this statement, and to class the commercial development of the arti-fiber or artificial silk mantle in this class of achievements.

The mantle manufacturer has held before himself for a quarter of a century and more certain ideals towards which he has earnestly striven. Some of these have been strength with elasticity, high and maintained candle-power, preservation of color and absence of shrinkage. A realization of these ideals seems finally to have been met in the mantle made from the bundle of elastic, spring-like fibers known as artificial silk, for the strength of these mantles certainly is something phenomenal, the high initial candle-power is not only maintained, but is frequently *increased*. This is made possible by the practical absence of shrinkage upon prolonged burning and by the very curious phenomen that this mantle does not seem to collect the fine mineral dust from the atmosphere as do those manufactured from the shorter vegetable fibers, cotton and ramie, this silicious dust having a very great affinity for the basic materials of the mantle body.

The attainment of this ideal has been reached only after years of persistent research guided by many more years of experience in mantle manufacture. Old theories had to be abandoned and former methods completely changed before this mantle was commercially possible. This was a chemical problem of great complexity, and its successful solution arouses such enthusiasm within me that I am tempted to include this among the radical and spectacular developments in our industry.

I have described some of the chemical problems connected with the manufacture of the incandescent gas mantle. There are many more that have to deal with the detailed process of manufacture of the mantle itself and with the economics of the industry, such as the conservation and recovery of waste products, but I will not weary you with a highly specialized paper. My chief excuse for treating the subject as I have done is to make it clear that each new type of mantle that is developed is an independent chemical problem from the beginning with the fiber of which it is formed, through every process and stage of manufacture, to the special collodion with which the finished product is finally prepared for transportation. I hope I have also convinced you that chemistry is just as essential for the successful operation of the incandescent mantle industry as it was in its inception and development.

Chemistry of Flaming Arc Carbons

Dr. **William C. Moore**, of the National Carbon Company, of Cleveland, Ohio, then presented the following paper on "Chemistry in the Development and Operation of Flaming-arc Carbons." The paper was fully illustrated by experimental demonstrations. We herewith publish it in full:

In an arc struck between two carbon electrodes, very nearly all the light comes from the incandescent electrode tips. In a direct-current arc, the positive crater is larger, and possibly at a higher temperature than the negative crater, and it is this positive crater which is the source of most of the light. Since the crater is merely an incandescent solid, it affords a continuous spectrum. Colorimetric experiments recently made by L. A. Jones and reported by him at the Cleveland meeting of the Illuminating Engineering Society, September, 1914, show that this incandescent crater has about 67 per cent of the daylight value of noonday sunlight. When volt-ampere readings are taken with such an arc it is found that if the arc is strengthened the voltage rises and the amperage falls, and eventually the arc goes out.

If we use as one of our electrodes a carbon rod which has been hollowed out into a cup, and place in the cup some potassium chloride, and again strike the arc, we find that the volt-ampere characteristics are changed and that at the same amperage a much longer arc can be drawn. Cassellmann in 1844[2] seems to have been the first to have noticed this fact. As we see, an arc fed with potassium chloride gives very little light; in fact, probably less than the pure carbon arc, as the positive crater is not so bright. This arc has a distinctive color, and, of course, would show, beside the carbon arc lines, the potassium lines in the spectroscope. Bunsen[3] in 1844 seems to have been the first to notice that different materials give different spectra in the arc.

If, instead of potassium chloride, we place a small amount of calcium fluoride in the hollow carbon cup, which, in this as in the previous case, is in the lower positive carbon, we find that the arc length for a given current and voltage is much shorter than for potassium chloride, and longer than for a pure carbon arc; moreover, the arc is intensely luminous, though rather un-

[2]Pogg. Ann. 63,576 (1844).
[3]Berzelius, Jahresbericht über die Fortschritte der Chemie und Mineral., 25, 20 (1845).

steady and liable to go out. On placing a mixture of potassium chloride and calcium fluoride in the arc, we get the combined advantages of a *long* arc, with more intense luminosity than is afforded by either the pure carbon arc or the potassium chloride arc alone. These simple facts form the starting point in the development of the modern flaming arc.

About 1899, Bremer, in Germany, brought out a flaming carbon, with calcium fluoride as the essential light-giving salt. The light afforded by such a carbon is a sensation yellow; the color is more aptly described, however, as "minus blue," as the spectrum of such an arc is very deficient in the blue.

From 1899 to the present the development of the flaming arc has been going on steadily and surely. It is interesting to note that the first record the National Carbon Company has of any work being done by them on the subject was when some ordinary cored carbons flamed and experiments were undertaken to prevent this phenomenon.

Although Bremer produced a carbon which could be burned vertically, for a number of years most of the commercial lamps were "inclined trim" lamps, taking long, cored carbons, which burned under open-arc conditions. A few years ago, however, there was developed a lamp for burning flame carbons in a vertical position, and for these lamps solid carbons have been developed. An interesting point is that the idea of solid carbons antedated the development of the lamps. These lamps generally operate in such a way that a limited supply of air reaches the arc; that is, under "enclosed-arc" conditions. These various types of lamps are doubtless familiar to the illuminating engineers present.

Modern flame carbons may be classified in several ways. From the standpoint of the mechanical structure of the finished carbon, we have cored carbons and solid carbons. From the standpoint of the color of the light emitted by the carbons, we have a major division in which are included yellow flame carbons and white flame carbons, and a minor division including red, green and blue flame carbons, red and green being but little used except for advertising purposes, and blue being used as a source of blue and ultra violet light for medicinal purposes.

In the major division, calcium fluoride is the chief constituent of yellow flamers, and rare earth compounds the chief constituents of white flamers.

A brief description of the method of manufacture of flame carbons may not be out of place. The first step, of course, is the careful weighing out of the requisite amount of the carbon base, and the proper flame materials for making a "mix." Most of these mixes are rather complex. After weighing, the ingredients are very thoroughly incorporated together and with an appropriate binder—generally tar, or pitch or a mixture of these. The "mix" is then forced by means of a hydraulic press, into long rods, which after cooling are cut into the proper lengths. These green carbons are then carefully baked in gas-fired furnaces and the temperature gradually raised according to a definite schedule, the final temperature attained being determined by a number of factors, such as the liability of some of the constituents to volatilize, or to react with each other and the carbon.

After cooling in the furnace, the carbons are unpacked, sorted, cleaned and gauged, the latter process consisting in determining the diameter, as but small variations in diameter are permissible; the carbons must also be quite straight. Some solid carbons are electroplated with copper, on the holder end to make a better contact between the lamp holder and the carbon. After plating, they are dried and made ready for shipment.

It is, of course, necessary to keep all flame carbons dry, as water may cause reactions between some of the flame materials, or may set up on a carbon-copper cell with some of the soluble or partially soluble salts as electrolytes and thereby destroy the copper coating. Water has another detrimental effect as shown by W. R. Mott[4], namely to react with the carbon at high temperatures, forming carbon monoxide and hydrogen; the latter may not only accumulate in the lamp housing and cause the lamp to explode when started again, but rapidly conducts heat away from the burning arc and lowers its efficiency.

The manufacture of cored carbons is quite similar to that of solid, except that the carbon base is different, and in forcing the die contains a pin which makes the carbons hollow. After baking, sorting and gauging this core hole is filled with a mixture of a carbon base and the flame materials with an appropriate binder, and the carbons are then dried. As cored carbons are usually very long and of small diameter, a zinc wire is inserted into a small hole parallel to the core hole. This wire increases the conductivity of the carbon. In order to make a good contact with the carbon and the holder, the carbons are "silver tipped"—that is, first copper plated, then dipped into solder, which solders the zinc protruding from the holder end, to the carbon. Such a connection is a permanent one, and is far superior to the scheme of simply bending the zinc over at the end of the carbon as the zinc becomes brittle when the core is dried and is liable to break off.

We now come to the question of desirable operating characteristics for a flame arc carbon. First of all, such a carbon should be reliable. It has been pointed out by Steinmetz[5] that after high efficiency is attained, we can afford to sacrifice some of the efficiency for reliability and other desirable factors. As will be shown below, the flame arc is already of high efficiency, hence we place reliability as our first desirable characteristic.

We may consider reliability under the four heads:

1. Constancy of distribution.
2. Constancy of light flux.
3. Constancy of color.
4. Ability to start with cold points after the carbons have been in use.

The length of the arc has a great deal to do with the amount and distribution of light. As the arc lengthens, the voltage increases; it is stated by Hechler[6] that there is a maximum definite voltage for maximum efficiency, that is, some definite arc length gives the most light.

The part that chemistry has had in increasing the reliability may be briefly indicated. It is readily seen that a flame arc which burns brightly part of the time and dimly part of the time can hardly be said to have 100 per cent. reliability if all the other factors are high. It may happen that all the flame material is evaporated from a given spot on the surface of the carbon, thereby causing a pure carbon arc for a short time. Such changes, however, are now rare, as a great deal of constructive chemical work has practically obviated this feature. As another factor affecting the reliability of operation of flame arc lamps, is the formation of slag on the points or on the lamp mechanism, it is readily seen that the proper proportion of the flame constituents and the right kind of addition agents for preventing such slags are of great importance, and here again we find that extended chemical research has resulted in the development of carbons in which this source of trouble has been largely overcome.

[4]Mott, *Electrical World*, Dec. 13, 1913, p. 1220.
[5]*Gen. Electric Review*, 17,180 (1914).
[6]Abstract in *"Electrician"* (London), 69, 658 (1912).

It has been mentioned that the flame arc is of high efficiency. The following figures are from some regular routine tests made in the laboratory.

Lamp	Current	Kind of Carbon	M.S.C.P.	Arc Watts	Watts per Candle
Excello	A.C.	Cored—yellow	1220	363	.29—
Excello	A.C.	Cored—white	843	369	.43—
Excello	D.C.	Cored—yellow	1462	445	.30—
Excello	D.C.	Cored—white	875	450	.51—
G. E. Type W.	A.C.	Solid—yellow	700	397	.56—
G. E. Type W.	A.C.	Solid—white	808	394	.49—
G. E. Lynn..	D.C.	Solid—yellow	1181	409	.35—
G. E. Lynn..	D.C.	Solid—white	939	421	.45—

The slightly lower efficiencies with the solid carbons are due to the fact that they are used in enclosed lamps, to which the air has only limited access, and so in these lamps there is less oxidation of the carbon and the flame material.

Some work by Henry P. Gage[7] at Cornell University on the efficiency of the arc stream proper may be cited here. This investigator found that, with cored yellow-flame carbons the energy radiated as light from the arc stream was 39 per cent. of the total energy radiated by it; with the arc stream from cored white flame carbons 27.5 per cent. of the energy radiated by the arc stream was light energy. The entire yellow arc showed six candles per watt radiated, while the entire white arc showed three candles per watt actually radiated.

These values are for the spectral region between 3800 and 6800 Ongström units, and for alternating current at 13.5 amperes. The following data may be presented as to the life of flame carbons:

	Life in Hours. A. C.	D. C.
Cored, yellow.....	12.0	12.50
Cored, white.....	11.08	11.25
Solid, yellow.....	115.08	125.0
Solid, white	120.0	96.42

These figures show why the enclosed flame arc lamp is more popular than the old "inclined trim" lamp, using cored carbons.

Having indicated at a number of points the important part chemistry has played in the development of the modern flame carbon, let us now take up in greater detail some of the chemical aspects.

In the first place, the selection of the proper materials for the manufacture of flame carbons is to a very large degree dependent on the chemical properties of these materials. When we consider the carbon base, we find that the chemical behavior, as well as the physical behavior of the various so-called forms of carbon, differs with the type of carbon employed. To use an extreme case as an illustration, we know that the chemical properties of graphite differ greatly from those of lampblack. There are likewise similar differences between charcoal and lampblack; petroleum coke and retort coke. This, in part, accounts for a different carbon base being used for solid and for cored carbons.

To a greater degree than the proper selection of the right carbon base the selection of the right sort of flame material and the right sort of addition agents with this flame material has been a chemical problem. This is illustrated by the fact that to-day we know no better material than calcium fluoride for the main constituent of yellow flame carbons. I do not think I will exaggerate the matter in the least when I say that compounds of every compound-forming element have been proposed as proper substances to incorporate into flame carbons—some of them in all sorts of possible and impossible combinations.

Having selected the *right materials*, the right amount of each is our next chemical problem. That the candle power depends upon the amount of flame material is well known; more exact information on this subject, however, may be had from the following table, which is from some work done in our research laboratory by Mr. Wm. R. Mott, using cored carbons in an Excello direct current lamp:

Parts of calcium fluoride by weight	3	2	1	0
Parts of other salt by weight.....	0	1	2	3
Mean spherical candle power.....	927	1,058	765	574

As is seen, there is a maximum per cent. of each of the constituents which will give the most light. This is true with nearly every substance which may be added to the calcium fluoride, and when we consider that flamers contain three or more substances in addition to the main constituent, it is readily seen that the nice adjustment of all these substances to each other presents some very interesting problems. It also explains why so much of our knowledge has been obtained in an empirical way. It is, of course, understood that the maxima for different addition agents do not coincide.

The chemical control of the impurities present in the raw materials is of great importance. Silica, ferric oxide and alumina, as are well known, are common impurities in calcium fluoride, and it so happens that too much of these impurities will make a poor burning carbon. Silica is especially undesirable, as calcium silicate is very non-volatile and so is a frequent cause of slag formation. The analytical difficulties in determinations of fluorine, silica and rare earths in presence of each other and of carbon are very great.

The unbaked carbon is a poor conductor of electricity. It is also rather friable. In the baking, the binder is coked and the carbon is rendered homogeneous and conducting. This coking of the binder is the chief chemical change in the manufacture of the carbon.

We now have to consider what chemical changes may occur during the burning of a flame carbon, and how these may affect the light emitted from the flaming arc. There are three possible sources of light in the flaming arc: electro-luminescence, thermo-luminescence, and chemi-luminescence. We do not know to what extent these three factors affect the light radiation in any one case. We do know, however, that in general there are two types of flaming arcs, (1) those in which the outer sheath seems to be intensely luminous, (2) those in which the core of the arc seems to be more luminous than the sheath. With very few exceptions arcs of the latter type give light of the shorter wave lengths. We have here an arc into which calcium fluoride is introduced; it is a representative of the first type; here is an arc into which chromic oxide is introduced, it is of the latter type. King has recently reported[8] that in a tube furnace almost all of the spectral lines seen in the arc spectrum of titanium appear, so that it would appear that in some cases a large proportion of the light from an arc is due to thermo-luminescence, though all possibility of chemical change was not precluded by these experiments.

Oldenberg[9] has made a spectro-heliographic study of various arcs, with some interesting results: For instance, he concludes that in the sodium arc, lines belonging to the principal series such as the "D lines" are due to chemical reactions between the vapor and the air. Band spectra seem to be of two types: those of the first type are due to collisions of atoms, in the high temperature core of the arc. The cyanogen bands always seen in a carbon arc he ascribes to collisions between carbon and nitrogen atoms. Bands of the second type are found in the sheath of the arc; they are due to undecomposed molecules; the bands of the calcium fluoride spectrum are of this type. When we consider that the

[8] *Astrophysical Journal*, 39, 139 (1914).

[9] *Zeit. f. Wiss. Photog., Photophysik und Photo. Chem.*, 43, 133 (1913).

flaming arc is a miniature electric furnace; that Fremy[10] showed years ago that oxygen converts calcium fluoride into calcium oxide; that calcium oxide and carbon react to give calcium carbide and carbon monoxide, and that the other constituents of a flame carbon may react with calcium fluoride, with the carbon, with each other and the atmospheric gases, we see that it is possible for chemical changes to play an important part in the production of the light of the calcium fluoride arc. Each of the possible substances may play its part in this light emission.

In conclusion, I think we may safely say that the past progress made in the flaming arc art has been due to the co-operation of the chemist, the physicist, and the electrical engineer; the future progress will likewise be dependent upon their combined efforts.

It might not be out of place to point out that the behavior of any one substance in the arc is determined by the conditions surrounding that substance—it behaves according to definite chemical and physical laws, and that our knowledge of these laws for high temperatures is exceedingly meager. On the other hand, once these laws are learned, it will probably be easier to build lamps to suit the carbons rather than to make a carbon to fit any and every lamp. In the extension of our knowledge of these laws, chemistry and especially physical chemistry will play an important part.

The Quartz Mercury-Vapor Lamp

Mr. **R. D. Maily,** of the Cooper-Hewitt Electric Company, presented a paper on the quartz mercury-vapor lamp. After a description of the lamp, in which special mention was made of the ground seal of invar with mercury "lock," the author emphasized that the quartz lamp is a most convenient and inexpensive form of apparatus for the production of ultraviolet rays. He then discussed at some length the effects of ultraviolet rays, especially the sterilization of water, bromination of organic compounds, photographic plate reactions, linseed oil clarification, etc., and made numerous demonstrations. The evolution of the quartz lamp has also been a development in the manufacture of clear transparent quartz apparatus.

Gaseous Electric Illumination

Mr. **D. McFarlan Moore,** of the Edison Lamp Works of the General Electric Company, Harrison, N. J., presented a paper on "Electrochemistry and the Development of Vacuum Tubes, and the Moore Light."

The author gave an interesting account of his early pioneer work begun in 1894 on "filamentless lamps." He described how in his early experiments with vacuum tubes the illumination depended on the kind of alcohol used in cleaning the tubes, how the long-tube system was worked out, how both external electrodes and internal electrodes were tried. Many experiments were made on feeding a gas to a tube or generating the gas in the tube itself. In 1896 the feed valve was perfected and experiments were made with various gases. Most interesting from a commercial standpoint was nitrogen, because it produced the most light with the least electric power consumption. Later color matching outfits were worked out, and so on.

But an immense amount of research work remains still to be done, especially along two lines. First, as to the most suitable electrodes, and second, as to the properties of the individual gases. For each individual gas there is a most suitable electrode material. Among the gases neon has become most interesting in recent times. The author concluded with a sketch of various theories on gaseous conduction and luminescent lighting.

The Use of Hydrometallurgical Apparatus in Chemical Engineering*

BY JOHN V. N. DORR

This paper, although the title is somewhat general, will be devoted principally to a description of the apparatus with which my name is connected. It was prepared at the suggestion of President Whitaker who felt that it would interest chemical engineers to know of methods which have proved of definite value in metallurgical work where large quantities of material are handled with low costs.

Metallurgical engineering is really one department of chemical engineering in its broadest sense.

General Metallurgical Tendencies

Comparing metallurgical operations of to-day with the work of thirty years ago, we note that nearly everything is done on a much larger scale.

One reason for this is the general development of engineering knowledge with improved materials and the substitution of exact scientific methods for the old "rule of thumb" ways.

Another is the greatly increased demand for metallurgical products, the consumption of all the common metals having increased several times as fast as the growth of our population.

A third and perhaps most important reason is that most of the smaller rich ore deposits have been worked out so that we have been forced to attack the large low-grade deposits which twenty years ago were considered of no value.

This tendency is well shown by the treatment of the disseminated porphyry copper ores and the handling on a much larger scale of the lower-grade ores at Butte and in the Lake Superior district.

The introduction of mechanical power in place of hand labor has, of course, been as important a factor in metallurgical progress as in all other lines of endeavor.

The introduction of continuous methods in the different steps of metallurgical processes in place of intermittent methods formerly used has meant great advances.

Continuous work means invariable lower labor costs and a high load factor, thus assisting in lower power costs and interest charges. Where the change does not sacrifice control of the operation it results usually in allowing a large output of uniform nature.

As illustrations of this tendency towards continuous work in metallurgy may be noted the use of pan conveyors and rotary cylinder feeders in delivering ore to primary crushers, automatic weighing machines and belt conveyors for the transport of dry material around a mill. The belt conveyor is also in use in stacking tailings from leaching tanks and has been used to stack slime tails from an Oliver filter and dewatered sand tails from a Dorr classifier.

In smelting plants we see the use of mechanical roasters and sintering machines, such as the Dwight-Lloyd, with continuous removal of slag by granulation.

The change in cyanide practice has been quite marked. Where leaching was practiced the original means of removing slime was to collect the sand in tanks while overflowing the slime and then shovel or otherwise transfer the sand so collected to other vats for leaching.

Continuous separation, whether by cone or mechanical classifiers, has done away with this, and the sand

*A paper read at the Philadelphia meeting of the American Institute of Chemical Engineers on December 4, 1914.

usually passes directly to leaching tanks without coming to rest.

In slime treatment, whether of classified slime or the whole mill feed reground, Dorr continuous thickeners have made continuous settling feasible, and continuous agitation has replaced the charge system for the dissolution of precious metals, with a very definite saving in power, attention and first cost of the installation required. The Oliver continuous filter has come into extensive use for that step in the process, and it is interesting to note that the decantation process, the first method used for the recovery of dissolved gold from slimes, which was abandoned everywhere except in South Africa on the introduction of the modern type of filter when made continuous by the use of the Dorr thickener, is coming into extensive use again and displacing in some instances an intermittent type of filter.

Zinc dust precipitation when first introduced as an intermittent process could make no headway against continuous precipitation with zinc shavings, but since being made a continuous process by Merrill has come into extensive use in modern mills.

Interchange of Apparatus in Industries

One characteristic of technological work in the last few years that was not in evidence in the centuries preceding is the exchange of information among workers in different fields.

Although the total knowledge in the world has increased so enormously, and this has been called very properly an age of specialization, the specialist is expected to have a general knowledge of progress outside his own field to such an extent that he can profit by it in advancing his own work.

This has been made easier in metallurgy more than in chemical engineering, I should say, by the greater freedom among metallurgists in the exchange of data. A valid reason for this is that the metallurgist competes in a much greater degree with natural conditions than with other producers of the same product.

The price of gold is essentially constant whether more or fewer mines are operating and, while the prices of silver and the base metals vary with the supply and demand, the profits made depend so greatly on other factors, such as richness of the ore and costs of mining and milling, that I doubt if any producer would hope to get an advantage over the others by secrecy. In fact, there is a general understanding among the larger copper companies to-day for an exchange of information which gives them all an advantage in the combat with Dame Nature.

In manufacturing, on the other hand, there is theoretically competition for the purchase of the raw material and the sale of the finished product so that manufacturing costs and profits must come between the two, and any advance that can be made in reducing the former unless kept from competitors seems of no real benefit.

The cyanide process has been benefited by the adoption of methods and machinery from other industries and has made its own contributions in return for benefits received. Fine grinding has been aided materially by the adoption of the tube mill from cement grinding, and when dry crushing and chlorination on Cripple Creek ores was in vogue the inclined traveling screens used in clay working were of great assistance as were the dust collectors taken from Minneapolis flour mills.

Our early paddle arm agitators came from chemical works and the air-lift agitator, or "Pachuca" tank which succeeded them, was first used, I am told, in a powder plant in California.

The Dehne filter press, so extensively used in Australia, was another adoption from chemical industries, and the rotary drum filter was used in Syracuse as a dewaterer of chemical precipitates before the cyanide process was known.

As developed by Oliver, with means for washing and blowing off the cake formed, it has been returned by the cyanide operator to several industrial uses.

Various forms of vacuum and pressure "cake" filters, such as the Moore, Butters, Kelly and Sweetland, might be said to have their prototype in the potter's method of making pitchers. This is done by pouring "slip" into a plaster of Paris mould and when a solid deposit has been formed by the absorption of moisture pouring out the remainder of the liquid "slip" and drying the vessel thus formed in the mould. From cyaniding they have found their way extensively into sugar refining, alkali work and many other lines. The Merrill sluicing press is being installed in a large aluminium plant in the South.

In closing this general discussion I will say that, while the basic principles for the mechanical treatment of analogous materials are the same, great caution should be used in proposing the substitution of any method or apparatus successful in some other field for that now used. It is safe to assume that the latter is in use as a result of much study and gradual development, and its replacement should be preceded by a most careful detailed study of all the conditions of operation and purposes to be accomplished.

Suggestions as to such substitutions may be advanced tentatively, but an actual demonstration is worth a lot of theorizing. In introducing new methods we usually find troubles come where not expected, and apparent difficulties do not prove real.

The Dorr Apparatus—General

The apparatus which I wish to call to your attention was developed by me in the last ten years in the course of operating cyanide mills in the West. Each machine performs a certain useful function satisfactorily and economically, and I feel that you will agree with me that where similar work is to be done they are worthy of consideration. I do not mean, of course, that a machine adapted for handling a sandy pulp is necessarily the best type to handle an extremely light chemical precipitate, but I feel that where the operations of washing, settling or agitation are required they may be of service.

As a generalization, I believe I am safe in saying that machinery successful in operations where costs per *ton* are studied to a fraction of a cent, have possibilities where materials are handled on which costs per *pound* are watched. It is true, on the other hand, that the economies of continuous work decrease with a reduction in tonnage, so that each case has to be studied by itself. In discussing the apparatus I have of necessity quoted freely from my paper on the same read at the Salt Lake meeting of American Institute of Mining Engineers in August, 1914.

The Dorr Classifier

This machine was devised by me in 1904 to replace hydraulic cones for the purpose of making a separation of sand and slime at the mill of Lundberg, Dorr & Wilson at Terry, South Dakota. The method of cyaniding the gold ore in use at that mill was crushing to pass a 20-mesh screen, separating the sand from the slime, leaching the sand in vats by percolation and treating the slime after agitation and thickening by the Moore filter process. The machine proved such an improvement over the cones in use at our plant and elsewhere that it was rapidly adopted and has come into wide use.

It has been improved from time to time to meet new

conditions and as now manufactured is shown in Fig. 1, which illustrates the standard duplex machine.

The Dorr classifier consists of a settling box in the form of an inclined trough with the upper end open, in which are placed mechanically operated rakes or scrapers for the purpose of removing the quick-settling material from the open end, the liquid and slime overflowing at the closed end. Each rake is carried by two hangers, one at the sand-discharge end suspended from

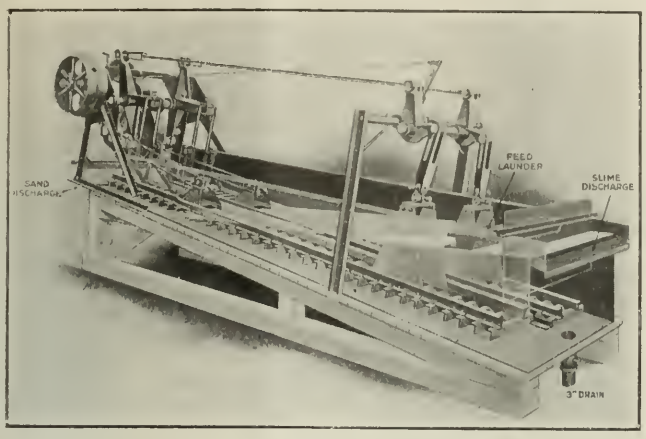

FIG. 1—THE DORR CLASSIFIER

an arm attachment to a rocker arm or lever which terminates in a roller. The other suspends from a bell crank connected by a rod to the same rocker. The roller is kept pressed against a cam on the crankshaft by the weight of the rakes.

The rakes are lifted and lowered at opposite ends of the stroke by the action of the cams transmitted through the rocker arms and bell cranks, and the horizontal motion is obtained directly from the crank.

The bell cranks at the slime end are carried by a second larger bell crank held in position by a chain attached to a spool on a worm gear at the head end of the classifier. By this means the rakes can be raised 10 in. at the lower end and operated in that position or any intermediate one. This allows the classifier to be started readily when nearly filled with sand after an unexpected shutdown, and the regulation of the depth of the settling box when in operation to vary the products being made.

The pulp is fed across the settling box as shown and a uniform flow to the lip at the end is maintained, while the sand settles to the bottom and is advanced by the rakes until it emerges from the liquid and is discharged with from 20 to 30 per cent moisture.

The agitation near the bottom of the tank caused by the reciprocating motion of the rakes assist in keeping the slime in suspension, but is not normally sufficient to cause fine sand to overflow.

REGULATION OF PRODUCTS

The machine is intended, of course, to make only two products, and the point of separation can be varied by the following means:

1. The use of the baffle shown, which allows a reduction of the cross-section of flow so as to overflow more fine sand.
2. Raising the rakes and thus obtaining the effect of operating them in a shallower tank.
3. Increasing the speed of the rakes until the agitation keeps fine sand in suspension.
4. The attachment of perforated spray pipes to the rakes at a point where they remove the sand from the liquid, allowing a rewashing of the sand and removal of any slime that may be carried down with it.

This latter feature will probably be of more interest from the chemical engineer's standpoint as enabling him to discharge finely divided sandy material and give it a complete wash to free it from any dissolved material which adheres to it.

CAPACITY

The capacity of the Dorr classifier depends upon the dilution of the feed and the point of separation which it is desired to make. The rakes of the Simplex machine, operating at normal speed, are able to discharge at least 150 tons of solids in 24 hours.

Table I, showing results at different plants, will give the best idea of what may be expected.

COST OF OPERATION

Experience has shown that repair costs on these machines are extremely small. I know of one classifier which operated nearly four years with repair costs of less than $5, and a half a mill per ton seems a safe figure. While the power taken will vary of course with the load, it appears that ¼ horsepower is ample in most cases. With normal feed the attendance required is practically nothing, being limited only to an occasional oiling. All parts in reciprocal motion are removed from contact with the liquid, so that there is no opportunity for wear starting at any point.

TABLE I—OPERATING DATA ON DORR CLASSIFIERS

Mill	Tons per 24 Hr.	Feed			Sand			Slime		
		Dilution	+100	+ 200	—200	+100	+200	—200	+100	+200	—200
Portland, Colorado	145[a]	5 to 1	38.3	13.4	47.1	75.3	16.2	7.4	0.9	5.8	94.7
Golden Cycle, Colorado	151[a]	3.5 to 1	45.0	19.0	36.0	68.0	23.0	9.0	...	11.0	89.0
Cia Benef. de Pachuca, Mexico	144[b]	4 to 1	42.7	25.1	32.5	43.6	40.1	16.8	0.1	3.8	96.8
Tonopah Extension, Nevada	73[c]	6 to 1	65.0	11.1	23.9	70.0	18.3	11.7	0.6	8.5	90.9

Nipissing, Canada	...	.....	78.7	3.6	16.8	85.8	7.2	6.9	...	0.5	99.5[f]

[a] New ore.
[b] Includes tube-mill return. Under normal conditions, with a tube mill in closed circuit with a Dorr classifier, 35 to 50 per cent. of original feed returned.
[c] New ore; tube-mill product returned, but amount not stated.
[d] 168 tons come from the stamps, the rest being returned from the tube mill.
[e] Classifiers used in connection with the regrinding of concentrator; rakes operated 24 strokes per minute; 100 per cent. of concentrates pass 200 mesh; the 2 per cent. is silica from tube-mill pebbles.
[f] Of this 200 mesh product 15 to 20 per cent. is sand; crushing is done in two sets of tube mills; the sand from the first classifiers being reground in closed circuit with the tube mills and other classifiers, the combined slime overflows giving the screen test shown.

USES

Besides being used to separate a leachable sand product from slime, Dorr classifiers are in general use to-day in connection with fine grinding.

Fig. 2 shows the arrangement of Dorr classifiers and tube mills operating in closed circuit in the Tonopah-Belmont mill. It is considered much more economical in power and equipment when a product 150 mesh or finer is desired, to pass a large tonnage continually through a tube mill, return the discharge to a Dorr classifier and overflow the part which is ground fine enough, returning the balance to the same machines for further grinding, together with the sand coming

from the new feed. This is considered much more efficient than to attempt to reduce the product to the size required in one passage through the tube mill. It seems more than probable that it will prove equally advantageous in connection with industrial pulverization of quartz, cement material and other mineral products that require fine grinding. Some work has already been done on thes lines, especially in connection with pigment grinding, but I have no data that are at present available.

Dorr classifiers are now in successful use as dewaterers of concentrates, both magnetic iron concentrates and sulphides, and are discharging the former at one plant with only 12 per cent. moisture.

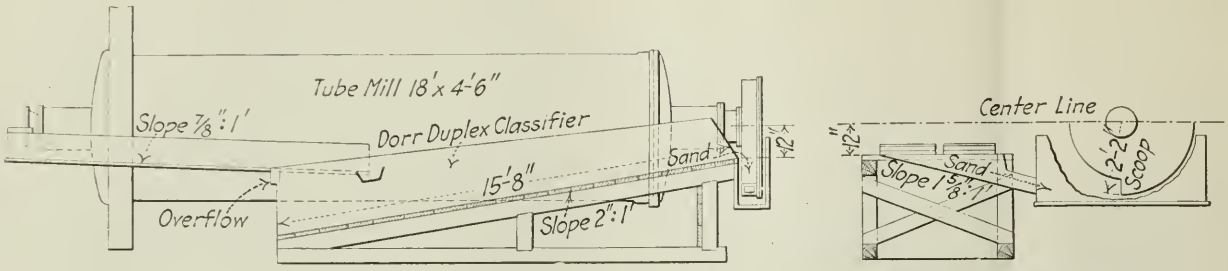

FIG. 2—ARRANGEMENT OF DORR CLASSIFIERS AND TUBE MILLS OPERATING IN CLOSED CIRCUIT IN THE TONOPAH-BELMONT MILL

LEACHING

The use of a series of Dorr classifiers for the purpose of leaching and washing was first suggested by Mr. Utley Wedge, and some experiments were made along that line several years ago but not carried to a conclusion. Last year Captain Wolvin of the Butte-Duluth Company at Butte, who was leaching oxidized copper ores in vats there, brought up the same idea and we furnished him with five classifiers for trial, with all parts, subject to contact with the acid, made of hard wood. These machines proved very successful, increasing the extraction over the former leaching in vats at least 20 per cent. and we have since then furnished them with more machines for the same purpose. Fig. 3 shows the discharge of tailing from the last machine of a series.

I have been unable to get reliable detailed results of these operations, as they have been changing details from time to time, but the following data obtained last summer from the Butte-Duluth Company, when the first installation, consisting of six small classifiers, was in use, will give an idea of the operations at that time.

6 Classifiers in series, 5-15′ x 4½′, 1-30′ x 4½′.
Ore crushed through .12″ opening in inclined impact screens, giving a product of about —10 mesh.

Value of heads	2.14% Cu.
Average strength, H_2O_4 acid used	7.33%
Ratio of solution to ore	2.25 to 1
Moisture in discharged tails	20%
Extraction	89.9%
Value of solution going to cells	1.8% Cu.
Value of solution from cells	9% Cu.
Speed of Classifier rakes, strokes per min	6
H.P. (motor 86% efficient)	4.6

The average daily capacity for the month in which the above figures were obtained was about 150 tons. The limit to the capacity was the lack of electrolytic cell room.

Spent electrolyte after strengthening was added to the first two classifiers and water into No. 6. Most of the overflow from the latter went to scrap iron precipitation and an amount equal to the acid liquor brought out from No. 5 with the ore was carried through Nos. 5 and 4 to No. 3, thus effecting a countercurrent washing. The overflows from Nos. 1, 2 and 3 after clarifying were sent to electrolytic precipitation. The ore received about 40 minutes' contact while passing through the whole series.

TRIPLE-WASHING CLASSIFIER

Fig. 4 shows a machine which we have designed to wash a sandy material absolutely free from any trace of slime or to wash the same kind of material entirely free from any liquid in which it may be suspended. It will be noted that there are a number of opportunities to get rid of the liquid or slime mentioned.

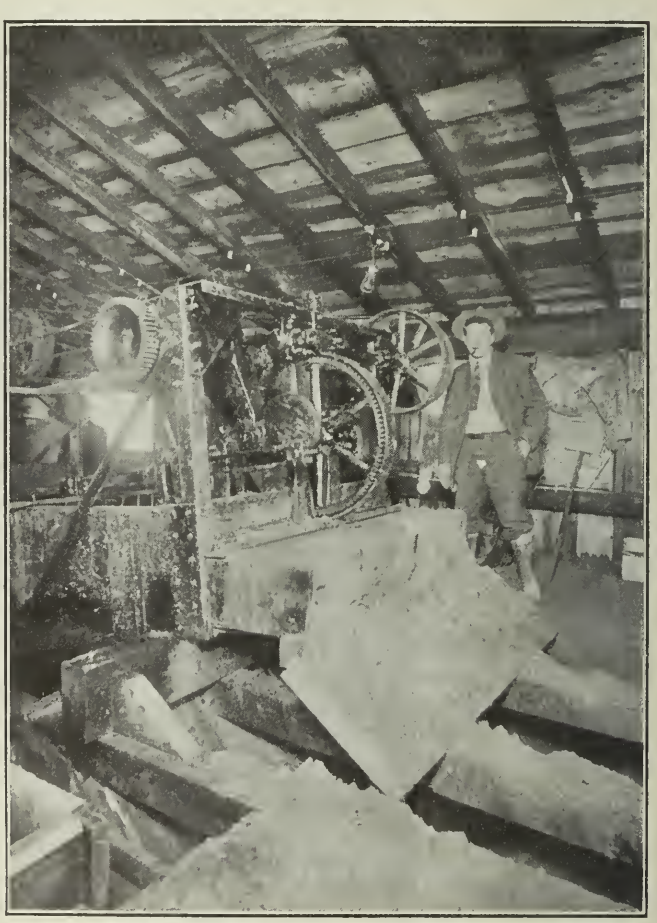

FIG. 3—TAILING DISCHARGE BUTTE-DULUTH COPPER LEACHING PLANT

First, as the sand is raked up above the water level in each box it is sprayed with any solution or water. Second, as it is washed into the following box it is diluted with the same liquid, so that in all it gets a very thorough treatment.

POSSIBLE USES OF THE CLASSIFIER

Several Dorr classifiers are now in operation at one of the mid-Western chemical works, used, I believe, for draining a granular chemical precipitate and washing same. Its use in connection with clay-washing in the preparation of a high-grade kaolin, in place of the settling boxes which now require a great deal of labor for removing the sand from them, is now being considered and its use for dewatering or removing granular material from any liquid will be apparent.

(To be concluded in the February issue.)

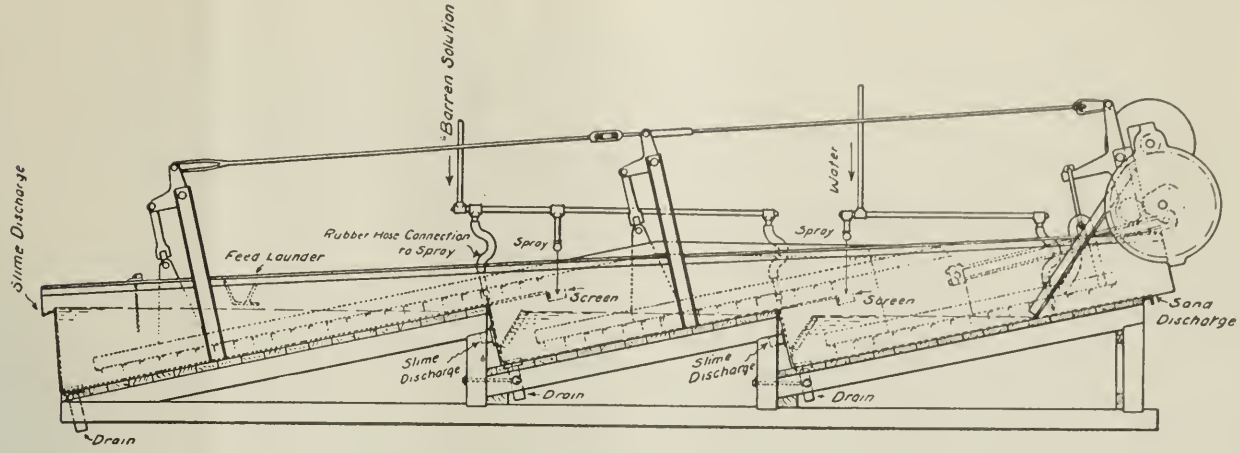

FIG. 4—THE TRIPLE-WASHING DORR CLASSIFIER

The Chemical Trade Situation in Germany and Great Britain

(From the London *Engineering*, December 4, 1914.)

The much-discussed subject of the control by Germany of a large portion of the chemical industries came before the Society of Arts [in London] on the two last Wednesdays in connection with two papers read respectively by Sir William Tilden and by Mr. W. R. Ormandy, D.Sc. Neither speaker took what we may briefly designate as the commercial point of view, nor did either enter into details of technical problems; Sir William Tilden gave a few statistics, Dr. Ormandy none at all. Both accentuated the general development of industry on methodical scientific lines, and as Dr. Ormandy adopted the more general and broader standpoint, we will begin with his lecture of last Wednesday.

Lord Moulton, the chairman, opened the proceedings by a few words, which made a deep impression. Speaking under visible emotion, and in terms which would have commanded the respectful assent of men of any nationality, he said that he had had to investigate the question of the supply of certain chemicals formerly obtained from Germany, and the facts were a cause for sadness and national humiliation. The chemical industry, except those branches which required least knowledge, thought, and least study, had, for reasons, perhaps, of our manufacturers being too well off, or of sluggish intellect, been allowed to fall into other hands. It was not that England was incapable or unfitted for the industry. They had to look for some fault in their national character or in their national behavoir, and they had to learn from the enemy. The most glorious moment in Prussia's history had not been their military success, but the period of deepest distress following 1806, when men like Fichte had not spared them, but had told them that only self-discipline and recognition of their national faults could help them to regain their self-consciousness and honorable position. Our position was not that of Prussia after Jena, but it was grave enough. Something more than contemplation of immediate profit was required; we had to rouse ourselves to save ourselves from German industrial domination, as well as from her military domination.

In commencing his remarks, Dr. Ormandy pointed out that when the introduction of the steam engine as a means of power and transport had rendered industrial development on a large scale possible, Europe outside the United Kingdom was in an unsettled condition, and this country could thus become the workshop of the world. British manufacturers paid low wages for long hours, and made enormous profits. Orders for steel and tools were given without much inquiry about prices, provided quick delivery could be guaranteed. The subsequent rapid development of foreign countries demanded capital for railways, shipping, mining, etc., and the best returns could be obtained from such ventures. English spinners and weavers were supplying the world with their products, while loom and mule machinery makers worked night and day to supply the infant foreign industries with the machinery necessary to compete with England in markets in which this country had held a monopoly.

The commercial life of Germany might be said to have commenced little more than a generation ago. An inland country, with little seaboard, few raw materials, no iron ores comparable to Cumberland hematites, and rather poor coal in distorted seams, Germany had seemed at a huge disadvantage. It was early recognized, however, that progress could not be left to individualistic effort. Too much credit could not be given to the far-sighted way in which problems of agriculture and industry were in Germany regarded from a national standpoint, while in this country [Great Britain] individualism was running rampant. The very people whose fathers had sold land to the railway companies at absurdly inflated prices now complained that, owing to the high freights, they could not make adequate profits from the investment of the money obtained from the same railway companies by an earlier extortion. In Germany afforestation was compulsory; enormous areas, fit for little more than potato cultivation, enabled Germany to produce glucose, starch and alcohol for all Europe. The iron exports, twenty years ago also insignificant, now exceeded the British exports by nearly 100 per cent. Realizing that all industrial progress was becoming more and more scientific, and that the adequate utilization of the by-products might settle the survival of the industry itself, by-product recovery coke-ovens, which also supplied the raw material for dyes previously obtained from England, were installed in the imme-

diate neighborhood of the blast-furnaces, and the surplus gas from both was utilized for power generation. Favored by Nature to an extraordinary degree as to pottery, English workmen had acquired a wonderful skill for the production of objects of art; but when the demand arose for complex porcelain castings of high-insulating capacity, Germany was able to secure that market.

The lecturer then passed to other features. Some one said that a nation got the newspapers it deserved. Judging by what had recently appeared in some portion of the [British] daily press upon German trade, it was devoutly to be hoped that the common-sense of the British nation would not be judged thereby. During the past ten years more than sixty millions of Germans had been fully occupied in industrial operations; our own [Great Britain's] population had equally fully been occupied, and yet people wrote as though there were a possibility that a large proportion of the activities of the larger nations could profitably be undertaken in a smaller country whose own workpeople had for the most part been quite busy.

Passing to the German willingness and ability to work in co-operation and to the great help afforded by banks to industry, Dr. Ormandy said that the heads of German banks were men of high technical knowledge, and not stockbrokers or retired colonels. These men were accessible to the inventor and ready to avail themselves of technical experts of the highest class to investigate new processes.

The other lecture upon "The Supply of Chemicals to Britain and Her Dependencies," which Sir William Tilden, D.Sc., F.R.S., delivered at the Society of Arts on Wednesday, the 25th ult., was more a plea for scientific research than a commercial review or a statistical compilation. "There is only one road to permanent industrial success, and that is the way pointed by science," was Sir William's advice to the chemical manufacturer. It was the old story in a new garb: chemical industry—some branches of it, at least—had migrated from this country [Great Britain], its original home, to Germany, and the country was now, the speaker said, in want of products which it ought to produce itself.

In his introduction, Sir William Tilden pointed out that Germany had contributed little to laying the foundations of theoretical chemistry a century ago. There had been no German chemist of the first rank, and only one fundamental German discovery, the discovery of isomorphism by Mitscherlich in 1819. Liebig, born in 1803, was the first of the great German chemists. If Professor Tilden had gone three years further back, to the beginning of the century in 1800, he would not have overlooked the birth of Friedrich Wöhler, a man whom chemists are justified in revering as one of the first men of his century and as the father of synthetic organic chemistry, in which, Sir William afterward remarked, "the most remarkable successes have been won, though not wholly, as sometimes represented, by the German chemist."

Turning to the position of industrial chemistry, Professor Tilden quoted the report on chemical processes and pharmaceutical products and processes at the second International Exhibition of 1862, by August Wilhelm Hofmann, then Professor of Chemistry at the Royal College of Chemistry and Mines: "The contributions of the United Kingdom have not only maintained their preeminence, but outdone their own admitted superiority on the corresponding occasion of 1851." Of 762 exhibitors in the class, 200 belonged to the United Kingdom, 136 to the Zollverein and 115 to France. The statistics of Allhusen and of Gossage showed that the production of heavy chemicals (alkalis, acids, manures, etc.) had nearly doubled between 1852 and 1862. Recent Board of Trade statistics proved that in these respects British manufacturers had no need to fear German competition in the home market.

But it was different in coal-tar dyes, drugs, antiseptics, essential oils, aromatic substances, materials for photography, pure chemical reagents, and the many other indispensable products of modern chemistry. The sources of supply of all these materials in the United Kingdom was seriously inadequate. In alizarin, anthracene, aniline, etc., dyes this country imported from Germany, in 1913, goods totaling £1,653,600 in value, and, further, £76,681 worth of synthetic indigo. Drugs, including medicinal preparations, were imported in the same year to the amount of £1,302,860, and more than one-fourth of these came from Germany, to which only £24,690 worth of coal-tar products were exported. No figures were available as to fine chemicals for analysis, but he might safely say that there was no appreciable production of these things in Great Britain. If that statement were to be met by protests from manufacturers, it was only necessary to refer to the experience of analysts and directors of research laboratories, who had habitually to resort to German makers for their supply of trustworthy reagents.

A chemical manufacturer, discussing the neglect of fine chemicals in this country, had recently remarked, "What does it matter if we are making money?" "I venture to say that that view expresses neither patriotism nor common sense," was Sir William's comment. German chemists were, indeed, attacking the market for heavy chemicals already. They, Sir William continued, exported three times as much sulphuric acid in 1912 as the United Kingdom did in 1913, and they arrogated the whole field of scientific and industrial chemistry to themselves.

In support of this statement, Sir William mentioned that Emil Fischer, in delivering the inauguration address of the Kaiser Wilhelm Gesellschaft zur Förderung der Wissenschaften, had suppressed every foreign name except that of Perkin. That is not quite correct; Sir William was rather severe, and he might, we venture to suggest, have clothed his allusion to that institution in such words as to further his own object—the promotion of scientific research. The facts are that large sums of money had been collected for the advancement of science; German chemical industry, though prosperous, wanted her institution for chemical investigation; the scheme became more and more ambitious, as money poured in, and to make further propaganda Emil Fischer traced in his address the relationship between science and chemical industry in Germany. It was a *pro domo* speech, not rich in names; there was no particular reason for introducing foreign names; yet, we grant, Fischer should not have confined himself to Kelvin, Perkin, Dewar, Berthelot and Baekeland.

In recalling the circumstances which had led to the gradual transference of the color industry from England to Germany, and to the failure to establish here any appreciable production of synthetic drugs and chemicals, Sir William Tilden regretted that A. W. Hofmann was allowed to return to Germany, where a Chemical Society was only founded in 1867, while the Chemical Society of London dates from 1841, and he blamed the antiscientific spirit and the neglect (up to 1885, at any rate, when Sir William Perkin commented upon it) of research by the old universities of this country [England].

That had quite been altered since then; yet it was necessary to insist that no man should be appointed a professor of natural science who had not shown his ability by original research, and the professor should have a sufficient staff of properly-trained assistants to

enable him to pursue a promising line of investigation. Forty years ago British chemical works had no qualified scientific chemists; in the palmy days of color-making hardly any British manufacturers probably had ever heard of Kekulé's benzine-ring theory, to which German chemists primarily ascribed their prosperity. German indigo had almost driven the Indian planter from the field; the value of natural indigo from India imported into this country [Great Britain] had fallen from £124,-112 in 1909 to £48,208 in 1913, while £76,861 worth of synthetic indigo had been imported from Germany in 1913, as mentioned above. "The strength of our competitors is in their laboratories, and not, as here, on the Exchanges," Professor Meldola had said. The maxim which we quoted in our first lines was indirectly suggested to Sir William by a lecture, delivered by H. Brunck, on "The History of the Development of Indigo," at the Hofmann House in Berlin in 1900, which lecture, Sir William said, "might be regarded as a sermon preached to British manufacturers."

In order to render the Empire independent of supplies from foreign sources, Sir William stated the industry wanted many first-rate chemists, a few engineers, plenty of capital, and some good men of business. It was right to learn from the enemy. British universities could supply the chemists if manufacturers would treat them more reasonably and liberally. The German large works took young university men on the recommendtion of the professors, placed them under the chief chemist of the department in the research laboratory, and paid them a salary sufficient to live modestly; their future depended upon their ability. The engineer was, of course, indispensable. As regards buildings, structures, supplies of water, fuel, power, and electricity, the engineer had the field to himself; but the chemist ought to be supreme as to chemical operations, and in the dye manufacture, *e.g.*, the chemist at present required little assistance from the engineer. We should submit, however, that in the practical adaptation of a process success will much depend upon the engineer. It has been acknowledged that Knietsch finally was able to make the contact sulphuric acid process a success because he was a first-class engineer as well as a chemist.

Sir William, in concluding, said that the establishment of what would practically be a new industry (after the war) would require State aid, and that aid had been promised to the dye industry; it would have to be extended to those chemical products on which the dye manufacturer depended.

In inviting discussion of the paper, Sir William Ramsay, the Chairman, in strange contrast to Lord Moulton, said that the Germans organized a chemical trade campaign as they organized a war. Expert committees looked out for new markets and raw materials, created a demand for them, had agencies all over the world, advised as to loop-holes in patents, and framed the patent laws so as to exclude the foreigner, all this with State aid bounties, export duties, &c. Some British works were, of course, quite as splendidly equipped as German works; but the small manufacturers had to be protected by organization, lest they cut one another's throats.

Professor James J. Dobbie, of the Government Laboratory, agreed with the lecturer, and referred to one point, the unreadiness of the British chemical manufacturer.

Professor A. G. Green, of Leeds, said that the question was simply one of knowledge; the Germans considered it worth while to pay for it, over here we did not. He would give a characteristic case. A firm wishing to take up a new explosive advertised, not for a chemist, but for a workman acquainted with the process; they got one formerly with a rival firm; he wanted fuming sulphuric acid, and the firm again advertised for a workman.

Dr. Chapman pointed out that in the science of brewing England was certainly in the forefront, to which the lecturer readily assented; he had deliberately omitted reference to brewing.

Mr. Walter Reid complained that the British inventor had to go abroad to get his invention worked. He had made the first smokeless powder, and offered it to the government, but his offer had been declined because they would have had to change their rifles. The British manufacturers were an untrained mob against an organized army. He had his doubt about government factories; the Board of Trade should really do something for trade, and be an advisory body; success of the National Physical Laboratory was largely due to the guidance it received from the general board, on which practical men had seats.

Mr. C. E. Cassal, of London, stated that if chemists were advertised for at £65 [or $325] annually, and Honors men were offered a final maximum of £150 or £200 [or $750 to $1000] as chief chemists, nobody could expect able men to select the chemical profession.

Sir William Tilden, in his final brief reply, repeated that the German works did not offer their staff more. Those men came direct from the universities, and had to learn their business first; no college could teach industrial chemistry.

Synopsis of Recent Chemical and Metallurgical Literature.

Gold and Silver

Precipitation of Gold from Solution—A method for the exact precipitation of gold from a solution, for example, after it has been separated from silver and platinum group metals, is given in the September, 1914, *Journal* of the Chem., Met. & Min. Soc. of S. Africa, by Mr. H. R. JOLLY. The solution of gold in aqua regia is "neutralized with a 20 per cent caustic soda solution. The beaker is then put on a hot plate, the contents warmed gently, and about 5 to 8 cc of a warm 10 per cent solution of potassium cyanide added, and the solution allowed to stand for about ten minutes. Thirty cc sodium sulphite 20 per cent solution are then added, and the beaker allowed to stand for about ten to fifteen minutes longer on the hot plate, after which it is removed and the contents diluted to about 300 cc. The process to follow is the same as the precipitation of a cyanide solution by Mr. Whitby's method. The reagents are added to the solution in the following order and quantity: 8 to 10 drops of 10 per cent potassium ferrocyanide, 30 cc of 20 per cent copper sulphate, 30 cc 20 per cent sulphuric acid, and 10 cc sodium sulphite. It is absolutely necessary to stir the solution after the addition of each reagent. The precipitate is allowed to settle and collected on a filter paper; after draining, the filter paper and its contents are put into a No. 1 assay pot, fluxed and fused in the ordinary manner. The lead button obtained is cupelled, the bullion bead parted and the gold weighed.

"Check gold was dissolved up in dilute aqua regia and treated as above. The following table shows the results:

Original Weight. ½ mgm.	Weight after Treatment. ½ mgm.	Loss ½ mgm.	Percentage Extraction.
24.54	24.50	0.04	99.83
34.74	34.73	0.01	99.97
30.44	30.44	...	100.00
10.22	10.20	0.02	99.80
26.45	26.40	0.05	99.81

"According to Watts' *Dictionary of Chemistry*, potassium auricyanide is formed by adding neutral gold chloride solution to a hot concentrated solution of potas-

sium cyanide, and it is on this reaction that the foregoing method is based. It is, however, necessary to reduce the gold to the aurous state in order to get complete precipitation, and this is accomplished by adding sodium sulphite."

Chemical Engineering

Removal of Sulphurous Acid from Fumes.—In an editorial on progress in fume recovery in our November issue (page 670) reference was made to a German invention for the elimination of sulphur dioxide from furnace gases by means of dicalcium phosphate. As several inquiries have been made concerning this process, we give here some details from the patent specification, although the patent is not of recent date (German patent 160940, class 12*i*, granted on May 26, 1905). The inventors are Eugen Bergmann and Theodor Berliner. If dicalcium phosphate is used as absorbent in presence of water, the sulphur dioxide decomposes the dicalcium phosphate according to the equation

$$2\ Ca\ H\ PO_4 + 2\ SO_2 + 2\ H_2O = Ca\ H_4\ (PO_4)_2 + Ca\ (HSO_3)_2.$$

This reaction occurs at ordinary low temperatures, and by this reaction it is possible to absorb the sulphur dioxide even from fumes in which it exists in great dilution. By a simple moderate elevation of the temperature to not more than 100 deg. C. it is then later possible to regenerate the dicalcium phosphate and recover the sulphur dioxide, since at the higher temperature the above reaction proceeds in the opposite direction (from the right to the left of the equation). The process is, therefore, cyclic with respect to dicalcium phosphate which alternately absorbs and gives off sulphur dioxide.

Lead Acetate Test for Hydrogen Sulphide in Gas.—The effect of the following factors upon results obtained in tests for the detection of hydrogen sulphide in gas by the lead acetate test has been investigated by the Bureau of Standards, Department of Commerce, and will be published in the forthcoming Technologic Paper No. 41 of that bureau: (1) The paper, kind, method of preparation, including the strength of lead acetate solution used, and the moisture content when used. (2) The gas, its humidity, and the period and rate of flow. (3) The apparatus, its form and size, as determining the circulation of gas with respect to the paper. With gas mixtures containing various known amounts of hydrogen sulphide these several factors were studied one at a time and the following conclusions reached: (1) An operator, by giving consideration to the desirable qualities which are pointed out, can easily select the most suitable and convenient kind of paper after a trial of a number of samples; the convenience, but generally not the accuracy, of the test is affected by the choice. There is little or no difference in the sensitiveness of the paper prepared with lead acetate solution from 2 to 12 per cent in strength; a 5 per cent solution is recommended. Treatment of the papers with ammonia or carbon dioxide does not materially change their sensitiveness. It is recommended that the test paper be dipped in lead acetate solution, blotted, and used moist, since such paper gives the most reliable results. (2) The large effect of the humidity of the gas upon the test results is shown; but it is also noted that the use of moist paper with short test periods (not over three minlutes) gives results practically independent of the humidity of the gas. It is impracticable either to dry or to saturate the gas to a constant condition as to humidity, because of the probability of simultaneous change in the hydrogen sulphide content. (3) The rate of gas flow has some effect, but increases in rate produce less effect than proportional increases in the time of test. The general practice of making tests at 5 cu. ft. per hour is satisfactory; maintenance of the rate within the limits 4.5 and 5.5 cu. ft. per hour is sufficient. The time of test is an important factor in determining its sensitivity; the proper basis for selection of the length of test is treated in connection with the discussion of the quantitative and engineering significance of the tests.

The different forms of testing apparatus used may be classified into three groups, circulating, impinging, and penetration, these being distinguished by the manner in which the gas is brought into contact with the paper. The five forms of circulating apparatus tested were: The simple hydrogen sulphide tester, chosen for this work and designated in this paper as standard apparatus;; the Referees apparatus; the Young's sulphur and ammonia test apparatus; the small drying-tower form, and a large Woulff bottle. Only one very simple form of the impinging type was tested; and a single penetration apparatus, devised in the bureau, was used. The variation in the tests with different forms of apparatus is largely due to the variation in intensity of the gas currents and their direction in relation to the paper. In the small drying tower the test paper was suspended close to the rubber stopper bearing the burner and a much larger proportion of the gas came in contact with the paper than in the other forms of apparatus. Although the Woulff bottle had a larger capacity than the Referees apparatus it consistently gave a stronger test than the latter, showing that size alone is not a determining factor; the shape of the apparatus and the location of the paper relative to the inlet and outlet have an important influence. It has been generally recognized that a test in which the gas impinges on the paper is more sensitive than one in which the gas does not impinge; this is due to the better opportunity for contact of the gas with the reagent on the paper and to the small area within which the lead sulphide is concentrated. And a similar increase in sensitiveness is accomplished by causing the gas to be tested to pass through the paper, as is done in the penetration apparatus described. This increase in sensitiveness due to impingement of gas on paper seems to have been overestimated by some, however.

The important influence of the shape and size of the apparatus upon the result of tests made with it, makes clear the necessity of an exact specification of the form and size of the tester. It is therefore recommended that the specifications given for the apparatus which is used as standard in this work, be followed exactly in making the tests. When the test is made under definite conditions, the coloration produced is of quantitative significance as indicating the amount of hydrogen sulphide present in the gas. The results which are obtained by the procedure recommended as standard are shown to have the following significance. The test, if of one minute duration, will detect about 0.3 to 0.4 grain hydrogen sulphide per 100 cu. ft. of gas. But if the test is of 0.5 minute duration, about 0.45 grain of hydrogen sulphide is required to give a test; if extended to three minutes a gas of about 0.2 grain will give positive results. The Young's apparatus is slightly more sensitive than the standard form, but the Referees apparatus is less sensitive for it will scarcely detect 0.5 grain of hydrogen sulphide per 100 cu. ft. of gas when used with moist paper for three minutes at a rate of 5 cu. ft. of gas per hour.

The penetration apparatus is somewhat more sensitive than any of the forms of circulating apparatus. The sensitivity of the apparatus of the impinging type is variable, depending upon the rate of gas flow, distances of jet from paper, etc.; but under the most favorable conditions apparatus of this type is the most sensitive of all. No direct comparison can be made with the work of some of the previous observers, but it is certain that too great a sensitivity has been ascribed

to the procedures used by these experimenters. The commercial significance of the testing procedure recommended is pointed out. It is stated that many tests of similar severity and some a great deal more severe have been met regularly in the past, showing that the proposal is certainly not unreasonable. The method recommended for use is quick and convenient and gives reproducible results; and a simple and inexpensive form of apparatus is described which can easily be constructed by inexperienced persons without any sacrifice of the advantages due to exactness of specifications. The importance of conforming to the specifications, both as to the apparatus and the procedure in testing, is pointed out.

Recent Chemical and Metallurgical Patents

Copper, Lead and Zinc

Flotation of Carbonates by Previous Conversion Into Sulphides.—Since oils manifest a greater affinity for sulphides than for carbonates or oxides, Mr. JOSEPH T. TERRY, JR., of San Francisco, Cal., proposes by a patented process to convert such oxides or carbonates into sulphides and then recover the same by flotation concentration. The inventor has discovered that oxide and carbonate minerals of such metals as copper, lead, silver, arsenic, antimony, mercury, bismuth, tin, cadmium, etc., are superficially converted to sulphides by hydrogen sulphide gas, or water solutions of the same, and that these converted minerals are then readily separated from gangue by oil flotation. In a similar manner, the water-soluble salts of metals are converted to sulphides and made amenable to oil flotation. The process may be applied by grinding the ore in water, treating with hydrogen sulphide gas and agitated with addition of oil. The sulphides float and may be separated from the gangue and recovered for further reduction. (1,094,760, Apr. 28, 1914.)

Copper Hydrometallurgy and Electrolytic Precipitation.—In patents issued to Mr. GEORGE D. VAN ARSDALE, of East Orange, N. J., the inventor describes his preferred method of roasting, leaching and precipitating copper in ores. When the ore is rosted there should be enough sulphur present to provide at least two parts of sulphur for each part of copper, and the roast conducted so as to give the maximum amount of water-soluble copper compounds. These compounds are leached with acidulated water, the acid for the initial charge being added from an extraneous source. After the cycle of operations is well started the acid can be secured by adding liquor from a preceding operation, being generated in the course of the process. Following the first leaching operation, the ore is washed with a second solution, which is added to the first. If more copper remains, a third wash may be given, the resulting solution being precipitated on iron and run to waste. This waste of solution can be regulated to avoid accumulation of impurities in the circulating mill solution. The original solution obtained is precipitated electrolytically, using sulphur dioxide to prevent polarization by combination with oxygen at the anode, and reduce ferric to ferrous salts. The gas is added to the cells during electrolysis, serving to heat and agitate the solutions.

The hydrogen evolved at the cathode tends to combine with the sulphur dioxide, forming hydrogen sulphide which then reacts to form copper sulphide which will be precipitated with the copper. In order to avoid this, precipitation is continued only until about 80 per cent of the copper in solution is precipitated, after which it is found that further precipitation commences to throw out copper sulphide. With a 10 per cent solution of copper sulphate containing sufficient sulphur dioxide to prevent polarization and reduce ferric to ferrous salts, 10 amperes per square foot at between 0.7 and 1.2 volts is sufficient to effect precipitation of 80 per cent or the copper without throwing out sulphides. The original solution is approximately regenerated and used as before. (1,119,477-8, Dec. 1, 1914.)

Smelting Complex Zinc Ores.—A method of smelting ores containing zinc and other metals such as lead, copper, gold and silver, is patented by Mr. JAMES M. HYDE, of Berkeley, Cal. The fluxed charge of ore is smelted over a bath of slag or matte and out of contact with the gases of combustion used for producing the smelting heat. The zinc is volatilized, the lead reduced to bullion containing some of the precious metals, and the copper recovered as matte containing also some gold and silver. Two types of furnace adapted to the process are shown in vertical transverse section in Figs. 1 and 2.

Referring to Fig. 1, the furnace wall A encloses the heating chamber and retort structure B. The charge within the shaft K and retort B is heated by products of combustion from gas burners G, H and G″. The gases entering G and H have no access to the charge within the retort B, and the gas entering G″ plays directly on the layer of slag. Arches C permit the fused material to fill the lower portion of the furnace which is provided with tap-holes D, E and F, for slag, matte and metal respectively. Zinc vapors pass off through pipes M to condensers N.

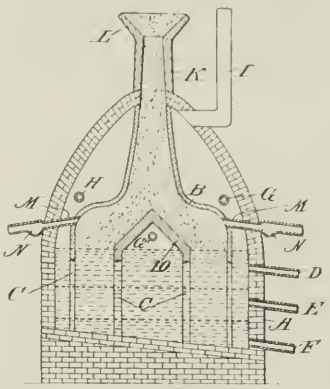

FIG. 1—FURNACE FOR COMPLEX ZINC ORES

In the modification shown in Fig. 2, the ore mixture is delivered through a hopper P′ to a tube L′ in which is a screw conveyor O′ to force the feed into the open-bottomed retort B′ extending transversely across the furnace chamber. There may be a number of such retorts suitably supported on a structure provided with open arches as in Fig. 1. The same tap-holes and condenser are provided.

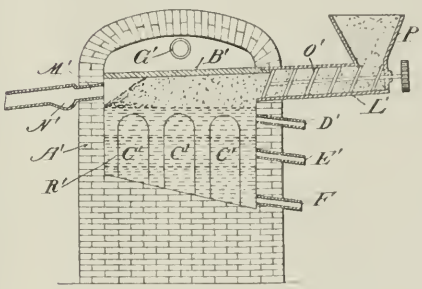

FIG. 2—FURNACE FOR COMPLEX ZINC ORES

In operation, the fluxed charge, either briquetted or loose, is fed into the retort where it is heated by the flame outside the retort. Volatilized zinc has a free exit to the condenser, and the fused materials fill the lower part of the furnace, from which valuable products containing the other metals are withdrawn. The process is claimed to offer economy in fuel, labor and mechanical wear and tear, as compared with present practice in retort furnaces, besides offering a possible means of treating mixed ores and recovering practically all the valuable metals. (1,118,012, Nov. 24, 1914.)

Mercury and Molybdenum

Extraction of Mercury.—A process for recovering mercury from its ores and other materials, is patented by Mr. E. BRYANT THORNHILL, of Gray Summit, Mo. The process was developed in connection with the recovery of mercury used for the treatment of high-grade silver ores at the Buffalo mill, Cobalt, Ont., but is appli-

cable to ores. The method is based on the solubility of mercury sulphide in a mixture of alkali sulphide and alkali hydroxide, and the precipitation of metallic mercury from solution by addition of aluminium dust. (1,119,377, Dec. 1, 1914.)

Extraction of Molybdenum.—According to a patent issue to Mr. Frederick D. S. Robertson, of Toronto, Canada, the ores of molybdenum can be treated for the production of molybdic tri-oxide by roasting at a temperature of about 800 deg. C. in the presence of an excess of oxygen. The volatilized product is collected in bags. The temperature in the bag-house must not exceed 120 deg. C. when woolen bags are used, or 90 deg. C. with cotton bags.

Data Concerning Platinum, the well known illustrated booklet, published by Baker & Co., Inc., Newark, N. J., has appeared in its thirteenth edition, with numerous new tables, illustrations and matter descriptive of various new appliances of platinum. There are 53 pages of descriptive matter of platinum stills for the concentration of sulphuric acid, platinum dishes, platinum parting apparatus, retorts, crucibles, combustion tubes, muffles, triangles, filter cones, platinum and platinum gauge electrodes, tongs, rods, etc. Concise useful rules follow on the use and care of platinum ware, as well as extensive tables of weights of platinum ware, sheet and foil, conversion tables, sulphuric acid tables, tables of specific weights, boiling points, etc. The whole book comprises 80 pages and is interestingly written and neatly printed and illustrated.

The Scientific Specialties Company is a new corporation with offices and show-rooms at 17 Madison Avenue, New York City. It will be the aim of the company to introduce new specialties in the chemical, metallurgical, physical and bacteriological lines, and to handle import orders for colleges, universities, etc. For this purpose a branch office has been established in Offenbach (Main), Germany. Radium and radium apparatus are one specialty of the firm.

The Industrial Instrument Company, of Foxboro, Mass., has mailed us its illustrated bulletins 86 and 91. Bulletin 86 describes the Foxboro differential recording gauges and orifice meters for measuring the flow of gases, about which we intend to give some further information in a future issue. Bulletin 91 describes the Foxboro recording and indicating dial-type thermometers, with several important recent improvements. Both bulletins contain typical and interesting records from the recorders in actual service.

Under Feed Stokers.—One branch, at least, of the iron industry has been benefited by the present business depression. Since the European war broke out orders aggregating ninety-nine of Hagan American Under Feed Stokers have been received by the George J. Hagan Company, Pittsburgh, Pa., from a number of the oldest companies in America to be used in varied industries from enameling light household utensils to heating heavy blooming mill ingots, so that the George J. Hagan Company has not only been able to keep its full force of employees occupied on full time and pay, but additional assistance in its engineering department has been required. For the Hagan American under feed stokers it is claimed that a cheaper grade of coal and less of it can be used to produce a given number of heat units and that these stokers are especially adapted to heating and annealing furnaces. Among those users who have given new orders recently are the Phillips Sheet & Tin Plate Company, Weirton and Steubenville Plants, National Enameling & Stamping Company, Scullin-Gallagher Iron & Steel Company, Crucible Steel Company of America., etc.

A Norwegian Electric Steel Plant

The Stavanger Electro-Staalverk A.S. has its offices in Stavanger, Norway, and its works at Jörpeland, across the fjord about ten miles east of Stavanger. At Jörpeland cheap electric power is abundant, being purchased from the hydro-electric development company at about $6.00 per mechanical horse-power year.

At Stavanger are some small shipyards, and also firms engaged in breaking up old steel ships. This furnishes a plentiful supply of old scrap steel, which has formerly been shipped to England and Germany,

FIG. 1—GENERAL VIEW OF STAVANGER ELECTRO-STAALVERK CO.

but is now basic material for the flourishing local steel industry. The capitalists of the ship breaking-up business are also largely interested in the electric steel plant.

The photographs show the plant at Jörpeland. Engineer Jacobsen is general engineer for the company. Mr. Th. H. Poulsson the manager of the works and Mr. Svensson metallurgist. The Siemens-Martin furnace has a capacity of four tons, and in it the scrap steel is melted by producer gas made from English coal. In about four hours the melted steel is transferred to a Roechling-Rodenhauser induction electric furnace, and

FIG. 2—CASTING FLOOR

there refined. The composition of the melted open hearth steel and of the refined electric furnace steel are about as follows:

	Open Hearth	Electric
Phosphorus	0.07	0.023-0.010
Sulphur	0.03	0.018-0.008
Carbon	0.10-0.15	As desired.

By adding ferro-alloys, various qualities of special steels, such as high-speed steel and magnet steel, are made.

The large foundry can turn out castings up to 8 tons in weight, by combining a heat in each furnace into one cast. The well-equipped forging plant produces rods and other shapes. Ingots and billets are being shipped

in considerable quantities to Sheffield, England, where they are forged and worked up into the finest "Sheffield Steel." This firm is selling large quantities of steel to England for motor parts for aeroplanes and automobiles; also a special quality of steel for hot-stamping, which is meeting with great success.

FIG. 3—FOUNDRY

The Stavanger Electro-Staalverk made a fine exhibit of its products at the recent Norwegian Centennial Exhibition at Christiania, and received a gold medal.

The success of the company is due to the combination

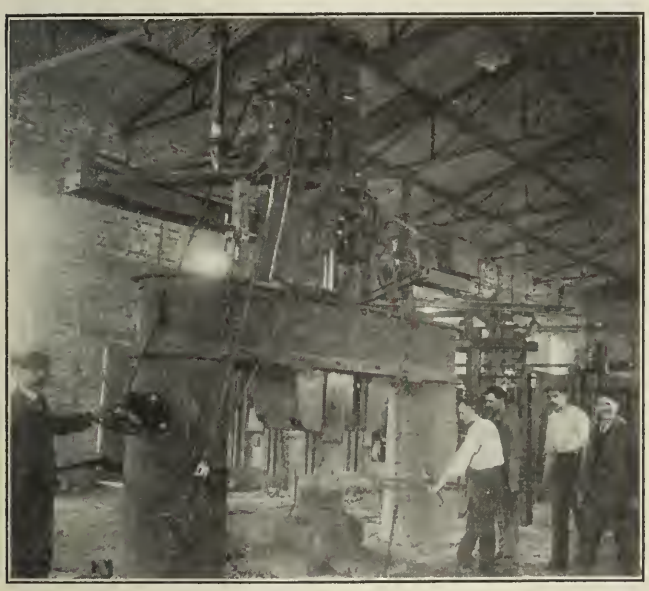

FIG. 4—FORGING DEPARTMENT

of the cheap supply of scrap steel, melting in the open-hearth furnace, refining in the electric furnace, cheap power, and able engineers and metallurgists in charge of the various departments of its works.

Personal

Mr. **H. F. Grondys**, representative of the Compania Minera de Oruro, Oruro, Bolivia, has been in Salt Lake City investigating metallurgical processes.

Mr. **H. W. Hardinge** has gone to Arizona for a three weeks' tour of the mining camps and to attend the American Mining Congress.

Mr. **Julius W. Hegeler** is president of the newly organized Hegeler Zinc Company, which succeeds to the business formerly conducted under the partnership of Hegeler Brothers. The company operates a zinc smelter at Danville, Ill.

Mr. **James M. Hyde**, of San Francisco, Cal., has been in Colorado on professional business.

Mr. **Woolsey McA. Johnson** has resigned as first vice-president of Johnson Electric Smelting Inc. His resignation will take effect on January 1, 1915. He will be

FIG. 5—CHEMICAL LABORATORY

connected with the company for the present in a consulting capacity and will remain a director.

Mr. **A. E. Keller**, of Denver, has gone to Ecuador to revise the mining and metallurgical accounting system for the South American Development Company.

Mr. **John L. Malm** has returned to Denver after a short trip east on professional business.

Mr. **J. H. Polhemus** has resigned his position as assistant to the president of the American Zinc, Lead and Smelting Company to accept a position as assistant manager of mines for the New Jersey Zinc Company.

Mr. **Walter Harvey Weed** has announced the removal of the office of the *Copper Handbook* from Houghton, Mich., to New York City.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

AQUEOUS BATH (ELECTROPLATING) *Continued*

655,111, July, 31, 1900, Andrew Plecher, of Savannah, Georgia.

Relates to portable apparatus for electrolytically decomposing solutions, such as water, into its components, hydrogen and oxygen. The apparatus consists of two parts of a vessel which when assembled is preferably of spheroidal shape. The parts may be of metal, suitably insulated, or of insulating material. The compartment in which hydrogen is evolved has twice the cubic capacity of the oxygen compartment. The compartments communicate with each other near the bottom, and have electrodes of either gold or platinum. Suitable outlets for the gases are provided, and an inlet for the solution to be electrolyzed, which may be dilute sulfuric acid.

664,550, Dec. 25, 1900, Henry L. Hollis, of Chicago, Illinois.

Relates to coating iron or steel objects with a protective coating of oxid of iron, and is an improvement

on his patent 621,084. The improvement consists in using an alkaline electrolyte, such as sodium hydroxid, passing a current therethrough with the iron object to be coated as cathode, whereby it is cleaned, then by a reversing switch changing the direction of current, making the iron object the anode, whereby it is oxidized. The electrolyte of sodium hydroxid has preferably a specific gravity of 1.25 to 1.40, heated to a temperature of 50° C. to 115° C., and with a current strength of 0.005 to 0.3 amperes per square inch of anode surface. The coated articles may then be heated in an annealing furnace for several hours at a temperature of 800° F. to 1400° F., which converts the coating to magnetic oxid.

665,784, Jan. 8, 1901, Henry K. Hess, of Philadelphia, Pennsylvania, Assignor to Herman J. Dercum, Trustee, of same place.

Relates to an apparatus for regenerating the electrolytes of two-fluid primary batteries, and consists of a lead lined tank containing a plurality of vitreous mercury troughs electrically connected as cathode, and a plurality of porous cells between the mercury troughs the porous cells containing lead as shot or scrap, or lead grids, connected as anode. The sulfuric acid electrolyte saturated with zinc is placed in the tank in contact with the mercury, and the reduced chromium solution placed in the porous cells. An electric current is passed which deposits the zinc in the mercury, liberating sulfuric acid, and re-oxidizes the chromium electrolyte. When the charge is regenerated, the mercury trays are removed, the zinc-amalgam pressed out, which may be pressed into amalgamated zinc electrodes, and the regenerated sulfuric acid and chromium electrolyte drawn off.

670,350, March 19, 1901, Botho Schwerin, of Munich, Germany.

Relates to a process of eliminating water or other fluids from solid mineral, vegetable, and animal substances, such as wood-pulp, starch-pulp, ground peat, disintegrated fruits, clay sludge, potatoes or beet-roots reduced to slices or pulp, distintegrated fish or flesh, crushed seeds, and the like, by the action of the electric current. The material to be treated is brought in contact with positive and negative electrodes by placing or moving it between the same while the current is passing. The molecules of water or other fluid diffuse from the solid particles toward the negative electrode where they are allowed to escape to the outside, for instance, by rendering the negative electrode permeable to liquids. The strength of current applied is dependent upon the nature of the fluid to be removed, and must be determined by experiments for each material. Mechanical pressure may be applied to remove some water and thereby reduce the current applied accordingly. For the apparatus used, see patent 670,351.

670,351, March 19, 1901, Botho Schwerin, of Munich, Germany.

Relates to apparatus for carrying out the process of freeing various materials of water described in his patent 670,350. It consists of two concentric cylinders, the inner electrically connected as the positive, and the outer as the negative, the latter being permeable, and may be of perforated sheet, or wire gauze, etc., and having an exterior covering of canvas or cloth. The inner electrode is supported upon a stationary shaft projecting into the apparatus. In the annular space between the electrodes is an insulated spiral, supported upon sleeves on the stationary shaft, and rotated by a pulley mounted upon the outer sleeve, thus moving the material forward. At the discharge end of the apparatus is a spring-pressed disk closing the discharge opening, and arranged to exert pressure against the material to keep it in firm contact with the electrodes and to press out some water through the permeable electrode.

670,510, March 26, 1901, William Friese-Greene, of London, England assignor to the Electrical Inkless Print-Syndicate, Ltd., of same place.

Relates to a method of electrically printing on paper, textile fabrics, etc., words, designs, etc., and is intended to replace the ordinary printing processes using ink or colors. The paper or other fabric is prepared by incorporating with it a photographic developer of the oxybenzene series, such as amidol, metal, or hydroquinon. The chemical may be applied in any suitable way, as by mixing with the paper pulp during the manufacture. The prepared paper is operated upon in a printing press or similar machine, the printing form or type being connected preferably to the negative pole. On passing the current the words or design to be printed appear upon the paper or fabric, and the operation may be performed at a rapid rate.

A variety of colors can be produced by this process, the color varying according to the substance with which the paper is prepared. When amidol is used, the paper should be washed in running water to remove the residual unchanged amidol.

Book Reviews

Coal Gas Residuals. By **Fred. H. Wagner.** 180 pages, 44 illustrations. Price, $2. New York: McGraw-Hill Book Company, Inc.

This book covers the handling of the gases of distillation to secure tar, naphthalene, cyanogen, ammonia, and benzol.

The treatment is detailed and practical costs of processes being frequently given, with estimates of probable profits.

The theories and processes of Dr. Feld are presented *in extenso,* and constitute a highly valuable source of information on advanced European practise, which American technologists will do well to study and to utilize.

Taken in the whole, it is a first-class book on a very timely subject.

Metallurgy of Copper. By **H. O. Hofman,** Met.E., Ph.D. Octavo (15 by 23 cm), xiv + 556 pages, 548 illustrations; price, $5. New York: McGraw-Hill Book Company, Inc.

Following his monumental work on general metallurgy, Professor Hofman has made the metallurgical world his debtor by a masterful work on copper. He is completing the series by revising his book on lead, and preparing treatises on gold and silver, and the minor metals.

This is a treatise on copper, for the modern copper metallurgist. In it he will find every branch of the subject considered, with copious references to the literature to enable him to push his studies further than the limits of this book. The compilation has taken an enormous amount of labor, and has been done with discrimination. The typographic errors are extremely few, considering the vast amount of data assembled. Professor Hayward, of Massachusetts Institute of Technology, assisted in the calculations interspersed through the work, which are both interesting and illuminating.

The discussion of bessemerizing of copper matte is very well done, particularly the thermal analysis. Throughout the work, drawings to scale are numerous, and comparative tables of practise in various plants are frequent. The work is everywhere "up to the minute." It is not so well suited for ordinary student reading, being so condensed and encyclopaedic, but will serve them well as a book of reference; it is a true *vade mecum* for the copper metallurgist.

The Debt of Transcontinental Telephony to Metallurgy.

The opening of the telephone line from New York to San Francisco on January 25 is one of the most noteworthy engineering achievements of recent times and sincere felicitations from every American engineer are due to Mr. John J. Carty, chief engineer of the American Telephone & Telegraph Company, and his able engineering staff. To the readers of this journal this event signifies again the interrelation of arts and sciences and especially emphasizes the fact that after all every new engineering undertaking must rely very largely on metallurgical progress. A few figures on the New York-San Francisco line are suggestive. The length is 3400 miles so that during any telephone conversation 6800 miles of wire are reserved exclusively for the speakers at the two ends. There are four hard-drawn copper wires of No. 8 B.W.G. gauge, from which two physical circuits and one phantom circuit can be derived. The total weight of copper in one circuit of two wires is 1480 tons. Of course, the whole thing would have been impossible without the high-conductivity copper obtained by electrolytic refining. But this was not enough, as Pupin's induction loading coils play an important part in the transmission, and in the construction of these coils iron plays an important part and the iron must have very peculiar properties; it must be as fine as a hair (0.004 inch in diameter) and must be insulated at that, and it must have very distinct electrical and magnetic properties. Some of the very best metallurgical talent in the world was employed in the solution of the problems involved. The work of designing and erecting the line has been enormous, but the achievement has been commensurate with the efforts.

Progress in Ore-Dressing in 1914

In the development of the art of ore-dressing during the past year, two tendencies were most distinctly marked. The first of these was in the direction of increasing the size and capacity of units of concentrating machinery. The second was the adaptation of flotation processes to an increasing number of types of ore.

The Utah Copper Company has for some time been making use of double-deck roughing tables having a very large capacity. The rough concentrate from a number of these tables is cleaned on a single table of the Wilfley type. A number of manufacturers are now offering special types of tables having unusually large capacity. One of the most interesting plants using a new type of an old machine is the slime concentrator of the Anaconda company, where twenty-deck buddles were installed for the purpose of handling large quantities of low-grade slime at low cost.

The engineers responsible for the development of concentration methods that have made possible the exploitation of the low-grade copper ore of the Utah Copper Company, designed a mill on similar lines for the treatment of the low-grade gold ore of the Alaska Gold Mines Company. This application of modern copper concentrating methods to gold ore is one of the most interesting developments of the year, but the conditions are unusual and the venture is expected to prove successful. The Alaska ore is amenable to this method of treatment because the gold occurs almost entirely in coarse particles. Jaw and gyratory breakers will be used for coarse crushing, and two series of rolls will finish the grinding prior to rough concentration. The next step in grinding will be done by tube or pebble mills, followed by the usual methods of concentration and amalgamation applicable to finely ground material. It will be observed that the almost universal practice of using stamps in connection with so-called free-milling gold ores has been abandoned in this instance.

Flotation concentration has now been in use by the Butte and Superior Copper Company long enough to demonstrate that the process, as specially modified by J. M. Hyde to fit the needs of that ore, is a marked success. Not only has the percentage recovery been increased by the adoption of the process, but the grade of concentrate also has been raised. It is understood that a special adaptation of flotation concentration has been developed at Anaconda to supplement the general milling scheme. The results are such as to make flotation appear a close competitor with the roasting-leaching process already perfected by the company's staff, and for which a 2500-ton plant has been erected. It is possible that flotation may be adopted for treating slime of current production, leaving the old accumulations to be treated in the leaching plant.

Experiments with flotation processes have been conducted by many prominent, and even minor, companies during the past year, and it is likely that the coming year will see a wider adoption of the process. It is expected that new installations in the large copper mills will effect so much higher recovery than is now being made as to materially augment copper production in the Rocky Mountain and Southwestern regions. Some engineers confidently see the doom of the vanner in the success of flotation, and if this be accomplished no one will regret to see the abandonment of the acres of vanners now necessary to handle the slime in the large copper mills.

A number of American engineers are contributing to the development of the art of flotation concentration. Mr. J. M. Callow has brought out a machine in which the air necessary for flotation of the oiled sulphides is introduced into the pulp under pressure through a canvas diaphragm. Mr. John D. Fields is sponsor for another process that has been tested in a number of mills, and was to have been adopted experimentally by the Ohio Copper Company, if that concern had not been overtaken by financial troubles. Mr. Henry E. Wood has developed still further his machine for surface-tension flotation, which is successfully applied to a number of types of sulphide ore. Mr. J. H. Haynes has made some novel improvements that look promising, having given encouraging experimental results. The Macquisten process has been in profitable operation at the Morning mill of the Federal Lead Company, at Mullan, Idaho.

In Australia, Horwood, Lyster and Bradford have brought out special modifications of practice for making a differential separation of sulphides.

Another modification of oil concentration, the Murex process, has been adopted on a commercial scale abroad and is being tested in this country. In this process finely ground magnetite is mixed with oil, which is then thoroughly mixed with the ore pulp to be treated. The presence of the magnetite in the oil permits the oiled metalliferous minerals to be removed by means of an electromagnet. The special field for this process seems to be in concentration of oxide and carbonate ores of lead and copper, and possibly in the differential separation of galena, pyrite and blende. In Germany it has been used successfully for recovering fine galena from slime containing much heavy spar. In Spain it is being used for the concentration of copper carbonates and oxides. Another patented scheme for floating oxide and carbonate ores involves their prior conversion, superficially, at least, into sulphides by treatment with hydrogen sulphide.

The art of flotation concentration should be rapidly developed when the status of flotation process patents is finally determined through the litigation now pending. Minerals Separation has succeeded in getting the United States Supreme Court to review the decision of the Ninth Circuit Court of Appeals in its case against James M. Hyde, and when the final decision is given, metallurgists will draw a breath of relief and progress will be rapid. It is regrettable that our patent procedure is so frightfully cumbersome.

Broadly speaking, the art of ore-dressing is becoming more complicated and more highly developed, and is constantly making it possible to treat materials that formerly were outside the realm of concentration. Professor Robert H. Richards has suggested that great profit is to be gained by placing high-class men in charge of the classifier departments of mills. In this regard it is certain that as we adopt new processes depending on principles not hitherto used, it will be more and more essential to employ high-class men in charge of ore-dressing operations; men who thoroughly understand what they are trying to accomplish, who know the principles involved, and who are capable of checking their work by the most carefully conducted tests.

A Failure in Coking Coal Land Speculation

Since January 18 the county court of Fayette County, Pennsylvania, at Uniontown, has been busy appointing receivers. On that date the First National Bank of Uniontown was closed by the federal banking authorities and immediately thereafter the receiverships began, for Josiah V. Thompson and many of his associates. Mr. Thompson's liabilities are stated at $22,000,000 while his assets are rated at $70,000,000. The interrelations of Mr. Thompson, his associates and various

corporations are so intricate and manifold that even a brief outline cannot here be attempted. There were partnerships, mortgages, options, promissory notes and other arrangements so extensive that Mr. Thompson, the central feature in all, and the president of the bank that was closed, is said to have been held at work twenty hours a day for a long time past keeping the financial and other machinery in operation. Finally the break came and it may be years before all settlements are completed.

While the structure that has been placed under the protection of the law until the engineers can repair its weak points or dispose of its parts is very complicated, the principle underlying the involvement is simple. Changes have occurred in the practices and ambitions of the steel trade of which the Thompson party was ignorant or became cognizant of when it was too late to protect themselves. A precedent was trusted when conditions had changed.

Mr. Thompson was a speculator in coking coal lands and carried with him almost the entire community which had money to invest. Almost the entire acreage in the regular Connellsville or "old basin" was acquired many years ago by merchant-coke interests or blast-furnace interests at relatively low prices per acre. In the latest period of its exploitation a few fortunes were made by farmers who had not earlier sold out. Just at the close of the last century the expanding needs of the iron industry required more coke and the lower Connellsville or "Klondike" was opened, and many fortunes were made. It was the spirit of the times that a large consuming interest should be provided with its raw materials for many years to come, and soon the Klondike was entirely pre-empted. Mr. Thompson, who had been prominent in the development, then turned his attention to the recognized extension of the seam across the Monongahela River into Greene County, believing that as the iron industry expanded it would be necessary for this coking coal also to be developed. His early purchases were at relatively low prices and his sales were by no means unimportant. They profited him while the buyers found themselves in fair position to ship coal or make coke. Year by year, however, Mr. Thompson paid higher and higher prices, whether to protect his market in selling coal acreage or through belief in the inherent value of the purchases it may not be safe to attempt to judge. The total acreage in which he is now interested directly or indirectly is estimated at not far from 200,000 acres in coal seams that promise to yield from 7000 to 9000 tons of coke per acre. This represents an amount of coke equal to the maximum shipments of the Connellsville and lower Connellsville regions for about three-quarters of a century.

In recent years the carrying of these speculative holdings has been expensive. It was necessary either that frequent sales should be made from the aggregation, at good profits, or that the recognized value of the coal, from the banker's standpoint, should increase steadily so that borrowings could be increased. Of late the sales have been infrequent and it seems to have been impossible to negotiate additional loans.

The operation was well planned in the light of fifteen years ago, for then there was no recognized competition for the Connellsville coking coal seam. It was the disposition of large blast furnace interests to fortify themselves for the future by acquiring ore and coking coal in the ground. The beehive-oven practice of the day naturally involved the acquisition of a large track of coking coal in the ground, for the ovens were located over the coal and enough coal had to be provided to give them a fair life.

While the development of by-product coking has involved many sad experiences, showing that the retort ovens also have their requirements as to the character of the coal to be carbonized, it is well established that the retort oven can draw from many districts, and of particular importance is the fact that since the retort oven is always located at the blast furnace, for well-known reasons, it is immaterial whence the coal comes so long as it is of the proper quality. Indeed, the builder of a by-product plant may prefer not to purchase a coal acreage at any price, but rather to remain independent and select his fuel as he proceeds—and learns.

The coal-shipping industry, being overdeveloped already, has not permitted any large development at anything but rock-bottom prices for the coal seam, and thus there has been little absorption of Greene County coal in that direction. It may be mentioned that one of Mr. Thompson's earliest customers, and his largest, the Pittsburgh Buffalo Company, has been in receivers' hands for some time. As to the use of the coal for coking purposes, styles have changed in the industry and therefore the object for which the Thompson coal holdings were accumulated could not be successfully carried out.

Apart from these purely technical considerations, it is well to reflect that there must be a limit somewhere to the activities of a steel-producing company. Even a corporation cannot do everything and do it well. Twenty years ago it was common for one company to make the coke and another to mine the ore. A third interest transported the ore, and a fourth interest quarried the limestone. Then the blast furnace assembled its raw materials and sold pig iron. There were steel mills that bought pig iron and sold billets, and "finishing mills" that rolled the steel. Since then vertical integration has become the rule. But the steel mill does not stop in its finishing where it stopped ten years ago. One prominent steel producer builds railroad cars. Several make cold-rolled shafting, car axles and the like. The largest steel-producing company in the world makes and sells automobile-engine flywheels. All the steel producers are called upon for heat treatment and for alloy steels. There is plenty to keep them busy, and to absorb their capital, without their mining coal or investing in coal lands. There was a time when such investments seemed necessary for defense but that time is past. Whether the Uniontown party did not know this, or acquired the information too late for it to be of service, is a detail in which the general public has no particular interest.

Carbon Determination by the Combustion Method

To the Editor of Metallurgical & Chemical Engineering.

A good scheme to reduce the cost of the determination of carbon in all metals and alloys in which the combustion method is used is as follows. The combustion boats after being used once or twice are no good for further use, but if they are cleaned of the insoluble fused mass, left after a carbon determination, they can be used again.

Several chemical houses have on sale electric polishing heads which with a high velocity (2000 to 3000 revolutions per minute) and fitted with a small emery wheel, the edges of which must be rounded, can be used to advantage to grind the fused mass out of the boats so that they can be used again. This wheel does not get into the end of the boat, but the small amount of the fused mass that is left, being carbon-free, would not vitiate the results.

These combustion boats are usually imported. With the grinding head, and with proper care in cleaning, one boat can be used to determine a great number of carbons. Care must be taken in cleaning them not to let the emery wheel touch the ends of the boat, for this would cause them to break and chip.

Comparisons of Electric Resistivities at High Temperatures

To the Editor of Metallurgical & Chemical Engineering.

Sir:—My attention has just been called by a friend to a draughtsman's error in chart 2 of my article, under the above heading, page 24 of your January issue, which I desire hereby to correct.

The curve for lead in chart 2 should of course correspond with the one in chart 1, hence the line approaching the short vertical melting point line should have been drawn to the bottom instead of the top, and the line after the melting point should have been drawn from the top instead of the bottom. The vertical line itself is correctly placed.

As this curve for lead is reproduced in chart 2 from chart 1 merely to show the proportions of the two scales, the error is not important except in that it gives the impression that the resistivity of lead falls upon melting, like bismuth, while as a fact it rises, as is correctly shown in chart 1.

Bismuth, antimony and perhaps Rose metal are the only three of the metals which fall at the melting point, all the others rising. It may be, however, that some of the non-metallic materials like those in charts 3, 4 and 5, fall upon melting, like bismuth; no data confirming this have come to my attention.

High Temperature Experimental Furnace

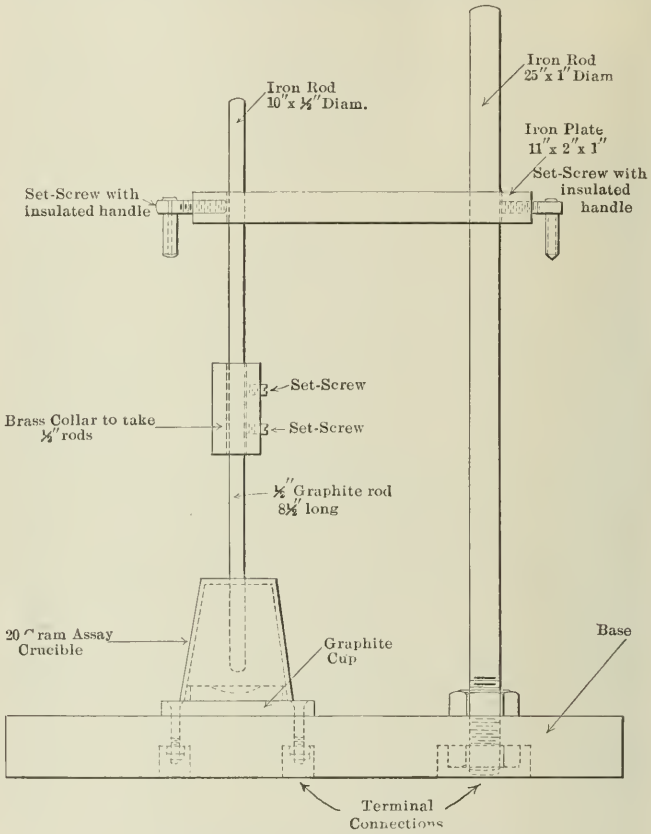
To the Editor of Metallurgical & Chemical Engineering.

Sir:—The following article describes a very simple and easily constructed experimental arc furnace which came under my observation while visiting the high-temperature laboratory of the Noble Electric Steel Company, at Heroult, Shasta County, Cal.

The furnace is especially adapted for the fusion of ferro-alloys, the melting point being reached within several seconds after applying the current.

The accompanying figure shows the furnace in its simplest form.

The base consists of a slab of any suitable refractory insulating material such as slate or marble. The standard is made by bolting an iron rod to the base at one end. A sliding arm, held in place by a set screw, holds the adjustable electrode. This electrode, which consists of a rod of graphite or carbon, slides through a hole in the bottom of an inverted 20-gram assay crucible



EXPERIMENTAL ELECTRIC FURNACE.

until it reaches within any desired distance from the bottom electrodes. The crucible serves the double purpose of protecting the eyes of the operator from the rays of the arc, and at the same time stopping any circulation of air which would tend to oxidize the electrodes. The bottom electrode is also made of graphite or carbon but in the shape of a disk in which is cut a cup for receiving the charge. Insulated handles of hard rubber are put on the set-screws so that the electrode can be raised or lowered while the furnace is in operation.

The furnace may be used on 110 or 220 volts taking from 30 to 50 amp while giving a ½-in. arc.

On starting a fusion it is better to cover the charge with powdered charcoal so that the crucible will fill with hot gas at the instant that the arc jumps.

Tube-Milling Tonnage Calculation and Notes on Tube-Milling

To the Editor of Metallurgical & Chemical Engineering.

Sir:—Fine grinding efficiency in tube mills, although of such universal importance, has thus far not proved

amenable to mathematical treatment, and although many other operations in the cyanide process are susceptible of fairly exact mathematical expression, tube-milling at all plants is, in the early stages of their operation, experimental. Many disconnected data are scattered throughout the technical press and although it is useful, the time would seem to have arrived when some of the phases of this problem could be given mathematical form. As a step in the right direction, Mr. Cunningham's contribution on page 22 of your January issue should create a lively interest, and it is hoped it will elicit much helpful discussion.

From Mr. Haynes' remarks I am forced to conclude that he does not consider the advantages of the closed circuit as by any means well settled, and were many others of a like opinion, Mr. Cunningham's contribution would be of little interest. However, I do not think Mr. Haynes' attitude is shared by any great number of cyanide operators and I do not feel that an analysis of his arguments will bring many to his point of view.

Mr. Haynes errs in placing too much weight upon *percentage* as a factor of gross tube-mill feed. What the operator is after is the percentage of the initial feed (net feed) which is ground to the desired fineness, and what gross feed the tube-mill handles is of very minor consequence to him as long as he feels he is securing a satisfactory net result. Theoretically, the tube mill should do its best work when it is relieved of the slime as soon as possible after it is produced, and this is the effect of the closed circuit from the very reason that the circulating feed (gross feed) is so large in proportion to the net feed.

To make this clear, let us add another line to his table II to exhibit the time element. The charge will maintain a substantially even level within the mill under all conditions, being determined by the level of the discharge opening, and any increase in gross feed will reduce the time any given particle is within the mill. The figures added to Mr. Haynes' table (we may conveniently call them minutes) have been based on this assumption, 80 tons being taken as 100 minutes, 109 tons as $80/109 \times 100 = 73$ minutes, and so on.

EFFECT OF VARYING TONNAGE IN TUBE-MILLS

Tons feed 24 hours.....	67	80	109	217	239	570	693
Per cent minus 200-mesh in discharge 30.03	30.15	20.04	16.56	16.00	10.28	8.09	
Relative time pulp is in tube-mill	119	100	73	37	33	14	12
Tons minus 200-mesh in discharge 20.12	24.10	21.84	35.93	38.24	58.59	56.06	

The time element as given above shows very distinctly why the "per cent minus 200-mesh in discharge" appears unfavorable with the large gross feed. The time a particle is exposed to grinding during one passage is but 14 minutes if it is part of the 570-ton feed, as against 100 minutes in the case of the 80-ton feed. With the large feed the particle may pass through the circuit a number of times if necessary, but many other particles may be reduced to the desired size in the first passage, after which they are immediately removed. Why keep such particles within the mill for 100 minutes when 14 minutes will suffice? Better exert the energy on other particles which are still too large. The closed circuit accomplishes this automatically.

The addition to table II merely serves to emphasize and explain what can be seen by inspection of the table as it appears in Mr. Haynes' discussion. I refer to the percentage of initial feed reduced to minus 200-mesh. Under 109 tons we find 21.84 tons, and under 570 tons we find 58.59 tons. That is, we have increased the feed five times to increase the finished product three times. But this does not necessarily indicate bad practice. On the contrary, inspection of the figures shows that to get 58.59 tons of finished product direct from 109 tons of feed about three tube mills would be necessary. From 109 tons, 21.84 tons were finished. This leaves 87 tons. From 80 tons (second column of the table) 24.10 tons were finished. This leaves 56 tons oversize and 46 tons finished, so that we would need a third tube-mill.

There can be no question as to which is the better result. A tube-mill consumes the same power regardless of how rapidly the pulp passes through it, and power is the large item in the cost of tube-milling. As in everything else, there is a point beyond which it is not economical to go in increasing the return feed, as wear and tear of classifier, cost of elevating the return, etc., come into play; but I do not think these factors set the limit in the case under consideration, but rather the direct flow of sands through the tube without being subjected to grinding.

What Mr. Haynes bases his arguments upon are conditions in which the tube-mill is overloaded, and in such cases considerable plus 200-mesh must overflow the classifier weir. These conditions are undoubtedly too common. In fact, he says at the end of his article: "Absolutely the only way to obtain a larger percentage of minus 200-mesh material in the final product is to increase tube-mill capacity," and in this I am in accord with him; but the increase can be brought about with fewer tube-mills if operated in closed circuit than if in series. In a large installation the series arrangement may occasionally work out to advantage by reason of the ability to suit the grinding conditions to the particular feed, which will differ in the second mill from the first; but Mr. Haynes' own figures show conclusively the superiority of the closed circuit, although he attempts to prove the opposite by them.

I believe the closed circuit in tube-milling is with us to stay, just as it is in roll-crushing, and that Mr. Cunningham's formula will be found useful by many operators.

H. B. LOWDEN.

Denver, Colo.

* * *

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I have read Mr. Justin H. Haynes' article in your issue of January 5, entitled Tube-Milling Tonnage Calculation and Notes on Tube-Milling, also Mr. Noel Cunningham's article on Calculation of Returned Feed to Tube Mills.

Mr. Haynes advocates tube mill capacity sufficient to grind the entire feed to desired fineness in one passage through the tube, claiming that the closed circuit is a mistake with no advantages. This does not seem to figure out from his own table, No. 2 on page 11, which contains the data given in Table I.

TABLE 1—EFFECT OF VARYING TONNAGE IN TUBE MILLS

Tons feed 24 hrs.	67	80	109	217	239	570	693
%—200 mesh in discharge	30.03	30.15	20.04	16.56	16.00	10.28	8.09
Tons—200 mesh in discharge	20.12	24.10	21.84	35.93	38.24	58.59	56.06

In accordance with this table it would seem that with 67 tons initial feed and the once-through process we would expect 20.12 tons, or 30 per cent, to pass 200 mesh; while should we run the mill on a closed-circuit basis, with 67 tons initial feed, in accordance with the table, when the return has built up to 570 tons we would have 67 tons overflowing the Dorr—58.59 tons of which would pass 200 mesh, or an overflow of which 87.15 per cent would pass 200 mesh.

Mr. Haynes states that it is no exception for a tube mill run in closed circuit to have a total feed of 7 times the initial feed. I feel that this condition is greatly exaggerated, Mr. Cunningham's deductions being much nearer the true condition.

Until a short time ago we had figured tube mill total feed, from screen analysis, about as Mr. Cunningham describes, afterward changing to calculation from plus 28 mesh material showing in feed from batteries which

150	6.6	74.8	24.4	85.7	28.6	59.2	12.5	13.5
200	4.0	78.8	7.8	93.5	12.7	71.9	14.2	27.7
—200	21.2	100.0	6.5	100.0	28.1	100.0	72.3	100.0

Tons crushed per day 500. Feed per mill 62.5 tons.

DEDUCTION FROM COARSE MATERIAL

In the battery discharge there was 41.8 per cent, or 26.12 tons, which did not show in tube mill discharge. This material was represented in total tube mill feed by 21.8 per cent. As we know this 21.8 per cent is represented by 26.12 tons, the 100 per cent feed should amount to 119.8 tons.

Total feed ..... 119.8 tons
Initial feed ..... 62.5 "
Return feed ..... 57.3 "
Ratio of return..... 0.92 to 1 ton

DEDUCTIONS FROM SAME BY CUNNINGHAM'S FORMULA

$$a = 21.2$$
$$b = 6.5$$
$$c = 28.1$$
$$d = 72.3$$
$$B = 62.5$$
$$T = X$$

$$\frac{T}{B} = \frac{d-a}{c-b} \text{ or } \frac{X}{62.5} = \frac{51.1}{21.6} \text{ or}$$

$T = 146.8$ tons total feed
62.5 initial feed
84.3 return feed
Ratio of return 1.35 to 1.

Not being entirely satisfied with deductions from screen analysis, a vertical baffle was made to divide a Dorr duplex classifier into two separate sides, or machines, running feed from the battery to one side and the tube mill discharge to the other side, taking from the discharge from both sides over a given time samples for tonnage by weight and screen analysis. Table III gives the results:

From the tabulated deductions we have:

Tons total feed..... 127.38
Tons initial feed..... 67.18
Tons returned feed..... 60.20
Ratio of return..... 0.91 to 1

I think the error in Mr. Cunningham's method is due to disregarding the coarser than 200 mesh material, which does overflow as finished product.

While I feel that tube mills in series have advantages, it is hard to accept Mr. Haynes' assertion that no advantage is had by mills working in closed circuit over the once-through method when mills are in parallel.

I would like to say in closing that the method of figuring tube mill return from the known tonnage in battery discharge, not showing in tube mill discharge which checks out very close to the actual figures from weighed samples, originated with Mr. F. C. Reynolds, who has charge of our experimental work.

A. H. Jones,
Mill Superintendent.

Tonopah, Nevada

The Iron and Steel Market

At the end of January the steel industry finds itself in no better position than at the begining, but the improvement that occurred during December has been maintained. The course of the market in January admittedly has furnished disappointment, not only because hopes were entertained, but also because expectations had been entertained that after the early days of January the December improvement would be continued.

The steel mills have operated during January at an average rate of fully 45 per cent of capacity, against an average of not more than 35 per cent during November and December. The current orders are of a miscellaneous character, there being no marked demand in any direction. There does not seem to be any replenishment of stocks in the hands of jobbers or manufacturing consumers. Such stocks had been subject to successive reductions, the last being occasioned by the tightness of money late in the old year, so that consumption was doubtless in excess of production in November and December while now consumption is at the same rate but production is somewhat heavier.

During the last five months of 1914 there was practically no buying by railroads. In the past month there has been an improvement, but viewed at long range the railroad buying is still very light.

Export demand is running quite largely to war material, both in the regular products of the steel industry and in the manufactured goods of its customers. The steel industry's exports are at record rate in barb wire, for instance, although the normal demand for barb wire from neutral countries has greatly decreased. Exports of lathes, motor cars and other things involved in war or the manufacture of implements of war are heavy. The latest export statistics are for November, showing 141,000 gross tons of iron and steel against 147,000 tons in October and an average of 141,000 tons a month during the first seven months of 1914.

It is clear that the steel market has not, thus far at least, responded as might naturally be expected to the great improvement in fundamental conditions, the heavy

export demand resulting during January in an enormous favorable merchandise trade balance, and the failure of foreign holders of American securities to dump them in our market, the result of these factors being a decline in exchange on London to below par while money for ordinary commercial purposes has become easy. In the circumstances the steel trade should be more prosperous than it is. There are hopes that the market will gradually broaden but there are no concrete developments in the steel market itself sufficient to support a a theory that it will.

A very sharp advance in spelter prices towards the close of the month created great excitement in the galvanized sheet trade, and prices advanced sharply, some mills, indeed, withdrawing from the market entirely until more settled conditions should develop in the spelter market. At the middle of October spelter sold at but a shade above 4½ cents, East St. Louis. At the end of the year it stood at 5½ cents, but in the week beginning January 18 it advanced from 6 cents to about 7 cents. A change of one cent a pound in the cost of spelter is commonly computed to mean a change of $3 per net ton in the cost of making galvanized sheets.

Pig Iron

The pig iron market has been quiet the past month, but prices have been well maintained. A general though somewhat restricted buying movement had occurred in northern iron late in the old year and the northern furnaces are in at least as good position as a month or two ago. The southern situation is anomalous. There was no general buying movement in southern iron, such as has always accompanied or even preceded a movement in northern iron. At the same time only two or three southern producers are free sellers, others holding to quotations that cannot let them into the market. Production has shown no distinct tendency to increase or decrease. The market is quotable as follows: No. 2 foundry, Birmingham, $9.50; delivered Philadelphia, $14.45 to $14.95; f.o.b. furnace, Buffalo, $13; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13; at valley furnaces (95 cents higher delivered Pittsburgh) Bessemer, $13.75; basic, $12.50; Nor. 2 foundry and malleable, $12.75 to $13.25. Ferromanganese on contract is nominal at $68, Baltimore, contracts being subject to embargo provisions that have not been thoroughly worked out. Prompt lots can usually be picked up at $75 to $80.

Steel

After covering nearly all consumers of billets and sheet bars for longer or shorter periods, usually the first quarter of the year, at low prices, averaging about $18.50 for billets and $19 for sheet bars at maker's mill the mills began to advance prices in January, Pittsburgh mills to $20 for billets and $20.50 for sheet bars and Youngstown mills by smaller amounts. Rods have stiffened to $25, Pittsburgh and some mills will not meet this quotation.

Finished Steel

Current quotations are as follows for ordinary deliveries, quotations being f.o.b. Pittsburgh unless otherwise noted.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.10c.

Shapes, 1.10c.

Steel bars and bands, 1.10c., base; hoops, 1.20c. to 1.25c.

Refined iron bars, Pittsburgh, 1.15c.; common iron bars, 1.12½c., Philadelphia; .97½c., Chicago.

Sheets, blue annealed, 10 gage, 1.30c.; black, 28 gage, 1.80c.; galvanized, 28 gage (uncertain), 2.90c.; painted corrugated, 28 gage, 2.00c.; galvanized corrugated, 28 gage, 2.95c.

Tin plate, nominal price, $3.20 for 100-pound cokes; large lots at $3.10 or possibly less.

Steel pipe, ¾ to 3-in., 81 per cent off list.

Steel boiler tubes, 3½ to 4½-in., 74 per cent off list.

Standard railroad spikes, 1.35c., Pittsburgh; 1.45c., Chicago.

Cold rolled shafting, 68 per cent off list.

Structural rivets, 1.35c.; boiler rivets, 1.45c.

Chain, ⅜-in., proof coil, 3.00c.

The Western Metallurgical Field

Spelter

The apparent steady improvement in the spelter market, as reflected by the upward trend of prices to six cents at St. Louis, is stimulating activity among producers of that metal. The outlook is regarded as very promising, and seven-cent spelter is freely predicted as a possibility before the close of the year. With the improvement in conditions, large producers are resuming operations. Butte & Superior is again operating its concentrating plant at Butte, and the new Timber Butte mill which treats ore from Senator Clark's Elm Orlu mine is also handling a large tonnage. The Granby company has begun smelting Joplin high-grade zinc ores at its new smelting plant at Roselake, Ill. This new smelter is situated near the coal fields of Illinois, in accordance with the tendency of building new smelters out of the natural gas districts of Kansas and Oklahoma. The furnaces are heated by producer gas, and the plant includes a sulphuric acid department.

The tentative proposal to erect on the Atlantic seaboard of this country a zinc smelter to reduce Australian concentrates which have been treated in Germany, received a set-back by the decision that the war does not abrogate the contract existing between the Zinc Corporation and Aaron Hirsch & Son. Australian producers have been placed in an awkward position by the fact that German smelters hold contracts for reducing the tremendous output of Australian concentrates. Apparently this precludes the possibility of smelting this material in the United States, or for that matter in England. The treatment of the Australian output in this country would be desirable from an economic point of view, as it would affect the whole industry in a manner favorable for the United States, but such an outcome does not appear possible now.

Joplin producers of zinc concentrates have been stirred recently by the belief that St. Louis quotations on spelter are not reliable and do not represent the true condition of the market. It is claimed that the quotations indicate prices for low-grade spelter, while the product of Joplin ore is of higher grade, commanding a higher price. As a consequence of these conditions, it is felt that Joplin producers do not get a price for their product commensurate with its grade. The Joplin Commercial club has been asked to attempt to rectify this matter by requesting the Merchants' Exchange of St. Louis to "adopt rules regulating the transactions in spelter which will make it possible for the exchange to stand back of and guarantee such quotations." At present the St. Louis quotations emanate from the Merchants' Exchange, but that body cannot guarantee their accuracy as it does on other commodities.

Consumption of Cyanide in Oregon

Supplementing the figures of the U. S. Geological Survey on cyanide consumption in the United States, given on page 743 of our December issue, we have secured from Oregon operators figures indicating an annual consumption in that state of 104,000 pounds. It

is expected that a new operator will commence work this year and augment the consumption by a small quantity. With the exception of California, the figures given in our December issue and herewith afford a complete statement of cyanide consumption in the gold and silver industries.

Alunite in Utah

Mention has been made previously in these columns of the existence of alunite deposits near Marysvale, Utah, which are potential sources of potash and aluminum. From recent reports emanating from Marysvale, it appears that the development and test of these deposits may be undertaken in the near future. It is reported that a contract has been let for the mining and transportation of 350 tons of this alunite to an eastern point, where experimental work will be done. In the event of a successful method of extraction being developed, a commercial plant will be established in Utah. The Florence Mining Co. is the concern doing this preliminary work.

Copper Leaching and Flotation Processes

Activity in developing and operating copper leaching processes for oxidized ore continues in a marked degree at several western points. At the same time flotation processes are being rapidly developed, and may have a decided effect on the future of leaching. In our last issue, page 63, we noted a patent granted to Mr. Joseph T. Terry, Jr., of San Francisco, California, for the flotation of oxidized ores of copper and other metals, by previous conversion of carbonate or oxide forms into sulphides by means of hydrogen sulphide, and then recovering the mineral by flotation as in the case of original sulphides. This method of "sulphide filming" and mechanical recovery may be found more advantageous from an economic point of view than that of leaching. At least it appears simpler to grind, convert and float ore containing oxidized copper mineral, than it does to handle the same ore by a hydrometallurgical process, with its large volume of circulating solution, incomplete extraction, economic limit of washing out dissolved metal, difficulties of precipitation, fouling of solutions, etc.

The sulphide-filming process admittedly gives a low-grade concentrate, due to the fact that the reaction between the oxidized copper compounds and hydrogen sulphide is so strong that particles of gangue containing even a minute quantity of copper will become converted to sulphide and thus float with the concentrate. It is understood, however, that further improvements in the application of sulphide-filming give promise of affording a method of producing a high-grade concentrate with practically complete extraction. Just what the final effect of this type of process will have on the future of leaching is difficult to forecast, but there is a possibility that progress in leaching may halt to determine the advantages of the new idea.

Chemical Control of Copper Leaching

A number of important analytical operations are involved in the control of copper leaching processes. Some of these are not exact, but give concordant results and afford quick determination to control mill operation. If the same methods are used on a variety of ores, comparative results can be obtained that will be valuable for reference. A solubility test can be made by treating 1 or 2 grams of ore in a beaker with 20 cc. of 5 per cent sulphuric acid (5 deg. Be., or 1.035 sp. gr.), allowing the mixture to stand for about 24 hours. The dissolved copper is filtered and washed from the residue, and determined by electrolysis.

The determination of free acid in the mill lixivium can be made by titrating in the cold a 50 cc. sample with standard sodium carbonate solution (1 cc. = 50 mg. H_2SO_4). The end point may be observed by the use of methyl orange, or the titration can be conducted without an indicator until a slight permanent precipitate appears after shaking. The presence of much manganese will vitiate the results, but with ordinarily clean solutions either method is satisfactory. If extreme accuracy is desired, the solution can be evaporated to dryness on a water bath. The residue is treated with absolute alcohol, filtered and titrated.

Iron will exist in both states of oxidation. Ferric iron is obtained indirectly by difference between total and ferrous iron. To determine ferrous iron, dilute say, 50 cc. of the liquor to about 200 cc., add 10 cc. sulphuric acid and titrate with standard potassium permanganate solution (1 cc. = 10 mg. iron). For total iron, dilute 25 cc. to about 100 cc., add sulphuric acid as before and boil with metallic zinc to precipitate copper and reduce all iron. Complete reduction can be determined by testing with KCNS. Cool and titrate as before, determining total iron. Copper in the mill solution is determined by electrolysis, and from the remaining solution the determinations for manganese, magnesium and lime can be made.

Company Reports

The ninth annual report of the *Consolidated Mining and Smelting Company of Canada, Ltd.*, for the year ended September 30, 1914, shows net profit from operations of $474,012, out of which four dividends aggregating eight per cent, or $464,376, were paid. The properties of the company are reported in good condition. The sum of $482,134 was spent on improvements at the smelter, comprising two Wedge roasters, conveyors and automatic scales for handling material in connection with the roasting plant, three new lead blast furnaces, Cottrell plant for precipitating fume from blast furnace gas, rebuilding three copper blast furnaces, installation of an additional blower having a capacity of 40,000 ft. of air per minute, rebuilding fire protection system, etc.

The additions to the roasting plant were necessitated by changes in the ore supply, demanding more capacity. The Godfrey roasters already in use had a capacity of only 25 tons each per day of Sullivan ore, whereas the two Wedge roasters recently installed have a capacity of from 85 to 95 tons each per day, and cost about 50 cents less per ton to operate, the saving being mainly in fuel. The cost of operating the Huntington-Heberlein pots has been reduced by the introduction of mechanical appliances for hand labor. The addition of a Cottrell precipitating plant was necessitated by losses in blast furnace gases. Since completing this installation, about eight tons per day of lead product is being saved. The rebuilding of furnaces was made necessary by the deterioration of the old ones. Two of the copper furnaces have been enlarged from 300 in. to 420 in. in length, and from 42 in. to 50 in. in width at the tuyeres. The enlarged furnaces show an increase in smelting capacity of from 60 per cent to 80 per cent over the old ones. The changes made at the smelter during the past two years will result in sufficient saving in cost of operation and recovery to pay for themselves within the next two or three years.

The Electric Furnace Products Co., Ltd., of Saude, Norway, has been organized for the production of carbide and other electro-metallurgical products. The probable production is estimated at 60,000 to 80,000 tons annually, to be exported to the United States.

The Non-Ferrous Metal Market

There has been a distinct improvement in the non-ferrous metal market during the last thirty days. Copper and spelter especially have been very strong. Lead is inclined to be weak, with tin about stationary. The advance in prices has been substantial and it is felt that the improvement is warranted and will be maintained.

Copper.—Both domestic and export business has been good and prices seem to be firmly established. Prices have ranged as high as 13¾ cents, and a large business has been transacted at 13½ cents, New York.

Tin.—This market has recovered from a decline in the London market and prices are firm again at about 33¾ cents for January tin.

Lead.—Prices for this metal have fallen due to close competition between independent interests and the largest producer. The American Smelting & Refining Co. finally reduced the price to 3.70, which is the latest available figure. St. Louis market is quoted at 3.50@3.55.

Spelter.—Consumers have been buying heavily and steadily, and the large volume of business has resulted in advancing prices. Export business continues good in high-grade spelters, these brands commanding a premium. The New York price for ordinary grades is 6.02½@6.07½ cents, with St. Louis at 5.85@5.90.

Other Metals.—The aluminium market is quiet, with prices firm at 19@19¼ cents per lb., New York. Antimony is showing more firmness as stocks decrease, and prices for ordinary brands have raised to 14½@15½ cents, with Cookson's at 16½@17 cents. The New York quotation for quicksilver is $50 per flask of 75 lb.; the San Fracisco price is $49.

The Presentation of the John Fritz Medal to John Edson Sweet

On December 2, 1914, the auditorium of the United Engineering Society Building was filled to overflowing with a representative gathering of engineers and their ladies to see the presentation of the "John Fritz Medal" to John Edson Sweet, founder and president of the Straight Line Engine Company, professor of mechanic arts at Cornell University in its early days, the virtual founder of the American Society of Mechanical Engineers, of which he is a past-president and honorary member, and recipient of the degree of Doctor of Engineering from Syracuse University.

Gano Dunn, past-president of the American Institute of Electrical Engineers, presided and was supported on the stage by the members of the board embracing many of the most distinguished engineers in the country.

The manner of Mr. Dunn's presiding was so admirable as to call forth almost universal comment. He said all that was necessary without arrogating to himself the opportunity to make a speech; while his enunciation without being slow and therefore tiresome, was so clear-cut and distinct that every word must have been audible in the farthest reaches of the auditorium.

Dr. James Douglas, past-president of the American Institute of Mining Engineers, made a brief but suggestive address upon the ancient partnership between the miner and engineer, the former being first the dominant partner. He described how through the evolution of his manifold activities the engineer had first reached, and then passed in importance all his competitors in mining and industrial life, but Dr. Douglas pointed out that great as the engineer had become he would never be able to dispense with the miner, on whom he must depend for the materials upon which to practice his art.

Dr. Douglas was succeeded by Dr. W. S. Stratton, director of the United States Bureau of Standards at Washington, whose address consisted largely of a catalog and explanation of the activities of his bureau.

He was followed by Mr. John R. Freeman, past-president of the American Society of Mechanical Engineers, who told the story of the establishment of the "John Fritz Medal," the method of its award, and outlined the notable achievements of Professor Sweet in furthering the mechanic arts, in teaching sane and rational principles of design, and in applying what had been until then only curiosities in the way of scientific measuring instruments, to the construction of commercial machines, with the result of building machinery of a quality of which America at least up to that time was ignorant.

It was a clear, concise statement of facts without direct praise to the recipient, such as every engineer should be, and unfortunately only a few are, able to make.

It may properly be stated here that Professor Sweet has done surely as much, and perhaps more to introduce accurate methods of measurement into industrial life than any other man in America, having designed and made among the very earliest of the straight edges, surface plates, accurate squares, and michrometer calipers ever made in this country.

When he founded the Straight Line Engine Company some thirty years ago he applied these instruments and many others specially designed for the purpose, to the construction of his engine and put it on a plane of workmanship far beyond that of any other engine builder and equal to, if not beyond, the standard of the most accurate machine tools. This workmanship, combined with boldly original designing, resulted in putting his engine in a class by itself.

He did not try to maintain his lead by closing his shop to others and preventing them from following his methods; but, on the contrary, carved in the stone arch over the entrance door, there were the words "VISITORS ALWAYS WELCOME," which he made literally true, and in addition he licensed his rivals to use patented features of his design.

This shortened the period of his engine's pre-eminence but vastly improved the standard of high-speed engine building. Not only has he always offered priceless information freely, he has been blessed with the gift of teaching in its broadest sense, such as few men possess; the gift of putting into simple language the most difficult explanations and in such original and striking form that the hearer can not only understand but can scarcely forget them.

The writer can remember after the lapse of more than twenty years almost the exact language used in making many explanations of difficult points. This is true not only of technical affairs; in matters of ethics an instinctive knowledge of the right has many times within the writer's knowledge, found expression in simple language which seemed to put any but right conduct beyond consideration.

It has sometimes happened, though perhaps not very frequently, that a man had made wonderful achievements as an engineer, but in the minds of those who knew him best had spoiled it all by undue pride in his own accomplishments, denying others just recognition for their help or other defects of character impossible to forget in connection with the man, but this is not such a case. Professor Sweet is less widely known than he might well be in virtue of his great achievements because of his excessive modesty. It is probable that of all the hundreds there gathered John Edson Sweet was the only one who did not think that he deserved the "John Fritz Medal."

On his personal side Professor Sweet has always had a gift pertaining only to character, and never to achievements alone, of attracting to himself, from his earliest years down to the present time, those with whom he had been thrown in contact, and maintaining relations in many cases of positive affection with them, not for short periods, but for life.

It is probably not known to more than a few people that instead of the occasional birthday dinner which has been given to some distinguished men, Professor Sweet has been the recipient of this honor annually for every year except one for the past fourteen years, the one exception being a year when he was out of the country at the time for this annual gathering.

The dinner has been a small one made up of those whom Professor Sweet himself had spoken of as his "boys"; though most of them are now gray and many of them white-haired. The first of these dinners was held in 1901 in response to a suggestion from one of the "boys" that it would probably be a matter of great gratification to "Professor," as he is universally called, to see as many of the "boys" as possible gathered together at one time, his association with them having been scatered over a wide range of time and space, so that while each individual knew the names of many of the others he knew but few of them in person. The plan was carried out in complete secrecy as regards "Professor" at the annual meeting of the American Society of Mechanical Engineers in New York in 1901, since this followed by only a few weeks Professor Sweet's seventieth birthday, and was the easiest occasion on which to get together a large percentage of the "boys."

At the first dinner about forty out of a total of sixty who had been reached were assembled, and the memory of the delight with which "Professor" saw what had been for many years the dream of his life carried out, the foregathering of a large percentage of the "boys" at one time and place, will never leave those who had the privilege of seeing it.

The occasion was made the opportunity for the presentation of a watch with magnificent works, but a case of "Bower-Barffed" iron, suited to the quiet taste of the recipient, and embellished with a tiny bas-relief of the first Straight Line Engine.

This first gathering was so great a success in all particulars that it was voted to make it an annual affair, a plan which has been carried out ever since.

These are perhaps not matters of technical importance but they may help to give to those who do not know in person this year's recipient of the "John Fritz Medal" an idea of his character such as direct description alone could not do. It is doubtful if the receipt of the medal by any other American engineer would have given pleasure and satisfaction to so great a number as has this award. J. E. J., Jr.

A pyrophoric alloy patented by Anton Kratky contains 84 per cent rare earth or cerium, 8 per cent magnesium and 8 per cent zinc or its equivalent in cadmium. The alloy is said to be very suitable for lighting devices working on the strike principle.

The production of nitrate in Chile has been seriously affected by the war, and thousands of people have been forced into idleness. The problem of caring for the unemployed has seriously come up.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in October, 1914, was 60. The total quantity of ore milled during that period was 2,357,695 tons. There were 9854 stamps in operation with an average duty of 8.96 tons per 24 hours. Tube mills in commission numbered 294. The yield for the month was 733,746 fine ounces gold, the largest for the year.

Hearing of the Proposed Amendment of the Patent Laws

On October 8, 1914, Congressman Calvin D. Paige of Massachusetts introduced a bill in Congress (H. R. 19187), proposing an important change in the patent laws in especially two directions, namely, first, that a patent shall be granted only for the *process* of making a drug, medicine, or dyestuffs, and not upon the *product* itself; and, second, that any patent relating to the manufacture of drugs, medicine, or dyes, shall be actually worked in the United States within two years.

A hearing was held on January 13 and 14, 1915, before the Committee on Patents of the House of Representatives, Chairman William A. Oldfield presiding.

Congressman Paige made the opening statement in which he explained that he had introduced his bill for the relief of the textile industry of this country, the intention being to alleviate the dyestuff situation created by the European war and break the world-wide monopoly of Germany in dyestuffs. The bill is not intended to apply to all patents, but simply to the dyestuff industry.

A general discussion followed in which Congressman Herman A. Metz of New York was most prominent in opposing the bill. He denied that the finishing companies and woolen manufacturers were not adequately supplied with dyestuffs. "The dyestuffs are coming in in adequate quantities, and will continue to come in in larger quantities." The prices of dyestuffs to American consumers are higher by 25 per cent than before the war, but only 10 per cent is due to an increase in price of the manufacturer and 15 per cent to the increase in freight rates and insurance rates.

Mr. Metz denied that the compulsory working clause, after it had been introduced in England, had worked satisfactorily. Mr. Metz also emphasized that the Committe on Chemicals and Dyestuffs of the New York section of the American Chemical Society had expressed itself unanimously against a compulsory working clause (see this journal, Vol. XII. p. 754).

Mr. Metz emphasized that "a plant does not make dyestuffs; a patent does not make dyestuffs; it is the material necessary to make them with. Those materials we have not got here, and we will not have them for some years to come. It is an interlocking proposition. . . . The question of patents we have had for years. Manufacturing it is really a question of tariff. There are 900 articles free, and there are only about 5 per cent of articles that are patented."

Mr. Georgii pointed out that the essential features of the manufacture of dyes in Germany are not so much based on patents as on trade secrets.

Mr. William G. Garcelon, attorney at law and secretary of the Arkwright Club of Boston, made a statement in which he said that the difficulty of the New England mills "perhaps goes deeper than the dyestuffs question, because the mills cannot sell their goods." They have bought a year's supply of cotton at somewhere between 13 and 15 cents, and now, when the price has dropped to 6 and 7 cents, the mills find themselves stocked with high-priced cotton and the buyers demanding goods on the basis of 6-cent cotton.

Mr. Garcelon would not now express himself definitely one way or the other as to the desirability of the legislation in question, though he discussed several points. "I am frank to say that I can go to certain men in Massachusetts today who have not discussed this question and I could get them to say, 'Yes, it is a fine thing; put it through; it looks good to me.' On the other hand, I am frank to say, I can spend an hour with them and present some of these things and they would say 'It is a bad thing; do not put it through'!"

Mr. JOHN H. BRICKENSTEIN, of the firm of Byrnes, Townsend and Brickenstein, patent attorneys, of Washington, D. C., emphasized that "this bill is making a fundamental attack on the general principle of the whole law under which patents are granted. It is not only an attack on that principle but it is for the benefit of a certain few, and is class legislation of the rankest kind." Against the proposition to make the bill general, the objection must be raised that this would deprive a patentee of one of his exclusive rights to his invention. In a rather amusing colloquy with Congressman Oscar Callaway of Texas, Mr. Brickenstein went to some lengths to explain that patents are granted in order to induce an inventor to disclose his invention.

"An inventor has got something worth while, and he will not disclose it, and Congress says to him, 'If you will disclose it we will protect you for 17 years,' and that is the inducement for the disclosure, and it has been that disclosure and the patents granted that have enabled the inventor to make money out of his invention, which has so enormously stimulated the manufacturing industry in this country."

Mr. Brickenstein argued that the bill would be in direct opposition to the existing treaty with Germany; further, in proposing to grant patents only on processes, not on products, "we will take away from the chemical manufacturer the most valuable kind of patent he can get. . . . Chemical process patents, as our courts are now constituted, are enormously difficult to sustain. The passage of this bill, with the elimination of product patents, would practically in this country take away every stimulus to the disclosure, which is the thing the law is after, the disclosure of any chemical inventions that are made. Everybody who could would keep them secret."

Mr. Brickenstein quoted from *Metallurgical and Chemical Engineering* (September, 1914) Dr. Hesse's exposition of the economic reasons why not more dyestuffs are made in this country. He emphasized that the way to begin a dyestuff industry is with the coke ovens.

A letter by Dr. BERNHARD C. HESSE, chemical expert of New York, to Mr. Metz was read in which he expressed the opinion that "there is no reason to believe that any good whatever will come from H. R. 19187 were it to be placed bodily on our statute books; on the contrary, all past experience allows of but one conclusion—namely, that H. R. 19187, if enacted into statute, would raise false hopes, and a false sense of security, and would miss fire absolutely."

DR. BAEKELAND'S STATEMENT

The most extensive statement of the hearings was made in the session of January 14 by Dr. L. H. BAEKELAND, of Yonkers, N. Y., president of the Inventors' Guild, past president of the American Electrochemical Society, the American Institute of Chemical Engineers, and The Chemists' Club. "The Paige bill aims at some evils which are supposed to exist in our patent system and which relate to the manufacture of chemicals. It would be useless to deny that certain of those evils exist. We know that certain foreigners take out chemical patents in the United States, not with the idea of working them but with the idea of preventing others from carrying out those patented processes. But such occurrences are relatively rare, and on account of this I think it is wrong to exaggerate any statements as to the extent of that evil.

"The Paige bill aims at suppressing the possibility of taking out a chemical patent without working it. The question is: Are the means proposed by the Paige bill the correct ones, and in suppressing the evil will the remedy not be worse than the evil itself?"

COMPULSORY WORKING CLAUSE

Dr. Baekeland first took up the proposal of the compulsory working of patents and recited how similar clauses have worked in other countries. He first spoke of Belgium. "Belgium has a patent law which provides compulsory working of patents. Belgium has, furthermore, a patent law which forbids the taking out of a patent for medicinal preparations."

"At the same time, Belgium can not boast of a chemical industry similar to that of Germany, neither in importance nor in variety, yet it would be very easy in Belguim to manufacture a large number of chemical products which are now made in Germany. I do not need to dwell on the spirit of industrial enterprise of Belgium. Belgium is a very highly organized industrial country, and in several industries outclasses the Germans—for instance, spinning and weaving industries, some metallurgical industries. But, what is more interesting, Belgium is the very country from which Germany gets the raw materials for the manufacture of aniline dyes.

"There is one detail which many of you probably have overlooked; that is, that when you speak about coal tar, which is the base of the aniline dye industry, any coal tar is not good for that purpose; it needs special coal tars, and it so happens that German coal tar is not so good, while Belgium coal tar is very good; English coal tar is good, too, and yet Belgium prefers to send its valuable coal tar to Germany and let the Germans fuss with it and produce many chemicals from it, which are exported and distributed the whole world over, and the Belgians buy back some of those dyes and chemicals manufactured by the Germans by means of the very raw materials sent there from Belgium." (In reply to a question by Mr. Metz, Dr. Baekeland said that the American coal tar is totally unsuitable for the profitable manufacture of some of those chemical products.)

"The Belgians prefer to weave cloth, spin yarns, make tissues, and to dye them with dyes manufactured in Germany. A few dyes are manufactured in Belgium, but the production of those dyes is a small industry; that is, as far as Belgium is concerned.

"In England a similar condition of affairs exists. England had introduced the compulsory working clause in her patent laws and had great expectations, as we always have before we try an experiment. It so happens that as far as the production of dyes is concerned, England is no better off than the United States. In fact, Mr. Metz forgot to mention the important fact to you that certain special coal-tar dyes are manufactured in the United States to a larger extent than in Germany or any other country in the world. It so happens that the manufacture of those particular dyes suits the special conditions of this country."

In answer to the question by the Chairman as to how the introduction of the compulsory working clause had worked in England, Dr. Baekeland spoke of the effect on a chemical process of his own. "I sold my patents in Europe, but on account of the compulsory working law in England we were compelled to start a special smaller factory in England. The market in England was so restricted that we could not to advantage organize the complete technical, scientific and engineering staffs nor the full equipment which is needed for conducting that particular enterprise in a profitable way with a limited market, and in England there has been every year a steady loss, so that we have to write off from the books every year a considerable sum of money. We are not able to produce in England all the different varieties of that particular product, for the reason that we could not possibly keep up a sufficiently large installation, and the result has been that England could not

be as well supplied with the many varieties of the particular product I am referring to. The question is being debated and will probably be decided in the affirmative that we shall be compelled to stop the manufacturing plant in England entirely. We prefer to forego the British market than to be compelled to work at a loss.

"I know that a similar thing has happened with other manufacturers. After a few years they came to the conclusion that it was cheaper not to take out patents in England after they realized that the market in England was too restricted for a complete and expensive chemical plant and organization. The same kind of logic applies to Canada, where they have also a compulsory working clause, which is further aggravated by the fact that you can not import in that country any goods patented in Canada without losing your patent rights, so that you can not even try the market possibilities before incurring the risk of building a manufacturing establishment. . . .

"The result is that many inventors—and I am one of them—have concluded that it is better not to take out any patents in Canada. Nobody will use your manufacturing process there anyhow; because if some one takes all the risks of starting a manufacturing establishment without patent protection, the next man can do just as much and follow his footsteps without incurring the risk of 'pulling the chestnut out of the fire' in starting an industry on an experimental scale." (In reply to a question on labor cost Dr. Baekeland explained that labor in the chemical industry plays a relatively insignificant part. "Our labor bill is predominantly for high-salaried chemists and engineers, scientific and technical men.")

Dr. Baekeland further pointed out that "in most countries the so-called working clause is an absurd farce. In Belgium and Italy and Spain it is sufficient to advertise in the newspaper that you are trying to give a license or that you are trying to make commercial connections for working your patents: in other countries all that you have to do is once a year to make some kind of a manufacturing operation before witnesses, and have them sign a certified affidavit that certain operations have been gone through as specified, and then you are all right for another year. Of course, that is rather expensive, but rich manufacturers, rich corporations, and rich inventors can afford it; poor inventors can not afford to do it. The result is that you will find that in most of those countries the poor inventors who have barely the means of paying their patent fees are 'frozen out,' while rich patentees are willing to take their chances, and therefore prefer to spend some money, which may look like a large sum of money for a poor inventor, but which for a large establishment is simply charged to general expenses, while they carry out religiously the formalities of the compulsory working clause every year. The result is that this just increases the general expenses of the manufacturing establishment and the consumer pays for it. It is charged under general expenses, like insurance and everything else.

"In England they have tried to be more drastic, and they specify how much of the material shall be produced in England, and by limiting the amount of patented material which can be imported, they stipulate that the patented material has to be manufactured in an adequate or substantial amount in England. It was just on account of this recent change in the patent laws of England, and during the first hesitation which was produced by this amendment to the law, that several American and German manufacturers started building factories in England. But the result has been that in many instances foreign patentees came to the conclusion that their British enterprises did not pay. Now they are willing to take chances, since they realize that after all if anybody takes up a process, of which the patent was allowed to lapse because the operation of that patent was unprofitable, nobody would care to operate it at a loss and they might as well import the product manufactured more profitably in another country."

With respect to Germany and its compulsory working clause Dr. Baekeland said he had made extended inquiries. "Practically without dissent everybody in Germany told me that the compulsory working clause there had proved of no value; and when I asked them, 'Why do you not drop it?' they said, 'for the simple reason that as long as we have this compulsory working clause we can use it as a retaliatory measure, as an act of reciprocity. We can keep it as a "club" over the heads of England, of France, and of all these other countries which are still pressing us with the compulsory working clause, and if you Americans were smarter you would help us do the same thing by introducing a compulsory working clause into your patent laws, with the provision, however, that the citizens of such countries which do not compel Americans to work their patents in their own country would be also exempted from compulsory working of their American patents.' He told me that this was the only reason why they decided to maintain the compulsory working clause in Germany.

"I believe if anybody wants to introduce from that standpoint such a measure in our patent laws as an act of reciprocity he can accomplish considerable good, but in that case this particular bill ought to be worded differently from the Paige bill." (Dr. Baekeland was here asked by the chairman to write out what he considered would do the work.)

THE PROPOSED SUPPRESSION OF PRODUCT PATENTS

As to chemical patents Dr. Baekeland emphasized how little the scope and purpose of chemical patents is understood by people who are not chemists. "In fact, to my great astonishment, I have found more and more that not only ignorant people but so-called educated people do not know what a chemical patent means. They think it is a patent medicine or something of the kind. Few chemical patents, or at least few important chemical patents, relate to pharmaceutical preparations. The scope of chemical patents is far broader, considerably more important from the general standpoint of industrial development and civilization." As examples of chemical inventions of far reaching industrial importance he cited the manufacture of high explosives, the process of making cellulose which gives cheap paper, the manufacture of aluminium, the cyanide process and so on. "Every one of those processes was a purely chemical process. When you begin to seek a difference between chemical and medicinal products, I can not see where to draw the line."

A chemical dyestuff may suddenly become a medicinal preparation. "There is, for instance, a substance which is called phenolphthalein, which is a dye of a red color and because it has such intensive dyeing properties, some wine producers thought it was excellent to use it for giving a peculiar red tint to their wine. They only had to introduce the smallest, infinitesimal amounts in order to obtain that particular red tint; but after they began to sell their wine there was suddenly in the whole district an epidemic of diarrhœa. By sheer accident they had found that the chemical which up until now had only been used for coloring purposes was a most efficient purgative."

"Chemists labor under great difficulties with their chemical patents. If we have a good patent we are continuously exposed to infringers, and the worst thing is most of the time we can not catch the infringers. As I have said, chemical processes require very few workmen. More than one chemical process is operated with

a single man, and often that man can produce 10 tons as easy as he can 10 lb.; in fact, with proper equipment it is much easier to produce 10-ton than 10-lb. lots for the reason that some of these industries can not be worked profitably on a small scale.

"Last year about this time I was spending about four weeks of my sweet life 'suing' one of the infringers of my patents, and the trouble was that it was very difficult, almost impossible, to establish infringement, because that man, who was a rich manufacturer, made the whole preparation himself; he did not allow a single workman to be present. He testified in court to that effect. We wanted to know what the raw materials were which he used. In Germany it would have been easy enough; in France it would have been easy enough; and in England it would have been easy enough, because the court would have appointed a confidential expert, bound to secrecy, to go into his factory and examine what he was using there. But our rules of evidence here in the United States will not allow this. So we had to establish what raw materials he was using, and therefore the judge directed him to bring before the court his books and invoices and the receipts, and the defendant simply said, 'I have no invoices, I have no records as to my purchases, and I burn all my receipted bills,' and there we stuck. This is not an isolated case. I could take up your time by giving you several more similar cases. . . . I am still waiting for the decision. I have waited a year now. The lawsuit cost me many, many times more than any damages I ever might be able to collect.

"Therefore when a chemist takes out a patent he first tries to see whether he can not obtain a product claim; if he can obtain a product claim, then it becomes easier for establishing infringements, and that is so true that the patent pirate will readily find some way to infringe a chemical patent which does not have a product claim. In Germany they allow no product claims for chemicals, but inventors there do not need them. We would be perfectly glad to have product claims suppressed, done away with, if we had a different and more efficient court procedure.

"It is not a question of patent law, it is a question of court procedure, it is a question of rules of court and broad interpretation of the claims of the patent; unless you can give us those improved rules of court procedure —and these are mighty difficult to introduce in the country where our very Constitution starts from another standpoint, where the rules of evidence are based on another kind of logic than that which impregnates the whole German code and the method of administering justice. If you suppress to us, gentlemen, our product claims you might just as well suppress all chemical patents. Our chemical patents do not amount to a large proportion anyhow. As far as I recollect, they only amount to about 1 per cent of all the patents taken out in the United States.

"But if you suppress a product claim in chemical patents why do you not apply the same rule for mechanical patents? Most mechanical patents are practically product claims. Why should you single out chemical patents? If a man infringes a mechanical patent you can easily detect the infringement, you do not need any detectives nor special chemical knowledge. We tried to use detectives once in the case of an infringer. We sent him to the infringer's factory and tried to get a small amount of the raw material to establish the infringement. The value of the material that man took amounted perhaps to 2 cents. He got arrested; he was indicted for larceny and put in jail. In the meantime they keep on infringing my patents. Why? Because when you sue on a process claim you generally can not get at the infringer except in certain cases. You could not break into one of those chemical establishments with dynamite; most of them use secret processes, and that is something which evidently Mr. Paige overlooked when he drafted the bill. I am sure he does not want to harm chemical industries, because his very bill aims at supporting chemical industries. He wants to back them up; he wants to make them stronger in the matter of competition with foreigners. He is perfectly justified in trying to do this, but unfortunately in trying to accomplish that result he is going to do incalculably more harm than the good he is trying to accomplish.

"I have nothing whatever to do with dyes or dyestuffs. I am not interested in that. I shall not talk of the commercial side of it, but I know that the situation is very similar to the situation in the manufacture of other chemicals with which I am better acquainted. The whole chemical industry here in the United States does not have to blush at all when compared with that of other countries. It is, in fact, remarkable that this country should have done as well in chemical industry as history proves. The world's electrochemical industry has been mostly developed by pioneer inventors here in the United States, and this division of chemical industry has taken tremendous proportions here in comparison with that of Germany, which has specialized more in the manufacture of dyestuffs; in both countries these specialties have developed in accordance with the natural opportunities offered by each of them."

THE CHEMICAL INDUSTRY AND THE TARIFF

"To give you some relative values, the United States is making one particular product which is called oleomargarine. The exportation of oleomargarine from this country to Germany was larger than the whole importation of aniline dyes from Germany. There are some other conditions which have produced quite awkward situations here in this country. Since our tariff law became a political issue instead of a plain business issue, and since the tariff has been changed and changed and changed over again, chemical manufacturers do not know where they stand.

"I will give you one concrete example, because I have been identified with it. I have just now before me a proposition which involves the construction of a manufacturing establishment of several million dollars. It so happens that right here in the United States a process has been developed for making a product, which I do not want to mention now by its real name but which I shall call B. In order to manufacture that product you need another product which is called A, which is the raw material for B. Now, this product A is manufactured in Germany by patented processes, and the corresponding patents exist also in the United States, but the patents are not worked here. You can not manufacture B profitably unless you get A cheap enough, but it so happens that some company here in the United States had a little bit of a factory in which A was manufactured by means of an inferior and absolutely obsolete process; it had succeeded in influencing Congress to put a prohibitory tariff on A, to the point of protecting it by 50 per cent of the selling price of A. In other terms, when Canadians or Englishmen pay, say, 10 cents for the product you have to pay 15 cents in the United States.

"It happens that that small American concern does not produce 10 per cent of the total consumption of that product A in this country. To make matters worse, the product B—which could now be made by means of an American invention, and which is at the point of being manufactured on a large scale, except for these particular difficulties—this product B is one of the chemicals which has been put on the free list. The

manufacturers of B, with our lax patent laws here, under which it is easy enough to infringe a chemical patent, might be disposed to take chances and infringe the process patents of the product A and manufacture the product A according to the German patented methods. Indeed the American patent disclosed the manufacture of the product A, but it is an enormously different thing—Mr. Metz is a manufacturer and knows that—to manufacture a product, and to manufacture it profitably. In other words, the yield of 10 per cent, more or less, or a slightly better quality, will make a process a losing business or a paying business. Now if any of these people here, in order to manufacture the product B, try to infringe the patent A, or even if the German patentees of the American patent A gave them that patent A for nothing, but would not communicate them their long experience in manufacturing, so as to obtain maximum profitable yields, the use of that process would be unprofitable from a commercial standpoint.

"In the meantime the result of this situation is that very probably this new American process—the process patented in America for producing this product B—will be compelled to go and locate in Canada in order to get cheap A imported from Germany into a country where A comes in free of duty, and after having manufactured B in Canada, it will be more profitable to ship this product to the United States, because B enters duty free in the United States although the raw material A from which B is made is loaded with an enormous duty.

"This is one of the many examples I could mention of the absurd conditions with which some of our chemical industries have to contend in this country. It is not only a question of chemical patents, but also a question of tariff and a question of raw materials. And then there is another matter which must not be slighted, although it has not yet been mentioned here. The matter to which I am about to refer should not be exaggerated; but it exists nevertheless. I know of instances where German manufacturers have said, 'If you manufacture such or such a product in your country we will make it impossible for you, because we have an establishment here which is so big and so complete that we can supply the demand of the whole world. We can not afford to manufacture profitably on a small scale, and therefore must keep our full units working; and we will undersell you in the United States, which will drive you out of business. In the meantime we will raise prices in other countries where we have no competition, so as to compensate for any loss we sustain in underselling you in the United States.' "

Questioned as to the chemical industries of this country and England, Dr. Baekeland thought that unbiased Englishmen themselves will acknowledge that of late we have gone ahead considerably farther than they have done. But "if we are speaking about English inferiority in chemical manufacturing, this is only relatively true. We cannot say that England is not still a very superior and important chemical manufacturing nation. And when it comes to some of the industries in which they are masters we must recognize that even Germany is second, and in whatever thing those countries have specialized it has been according to the lines of least resistance. The English textile industries and the English metal industries are so important in England that she can well afford to neglect some of her chemical dye industries or other mechanical industries, about the same way as in this country for a number of years we quite naturally gave far more importance to the industries of mining, transportation, and the mechanical industries generally. There was no need of chemical industries. It is not so many years ago that the manufacture of sulphuric acid on a large scale was practically impossible in this country. Why? Because there was no market for it. We are now, I believe, the largest sulphuric acid producing country in the world. I do not think there are any countries which produce more sulphuric acid than the United States. It required natural opportunities—the discovery of the phosphates to make superphosphates, the dynamite and explosives industry, the refining of petroleum in order to create a market for sulphuric acid.

"It is the same thing with the dye industries. The dye industries, unfortunately, are broken up into many little side branches, relatively small matters which in this country would by themselves be almost beneath the dignity of a man of enterprise to bother with. In Germany they can do it collectively, and why can they do it collectively? Because they can do a good many things there which would not be tolerated by the laws of this country. You all know—it has been mentioned here—that those German aniline industries make up an immense trust. They have agreements as to price, as to markets, and as to the restrictions of sale and restriction of production; and if there are any new patents, if one factory buys one patent the other can use that patent." . . .

"I visited one of those works. They do not look like factories; they look like well-organized towns. They treated me with unusual consideration, because they showed me what they very seldom do to visitors—several departments of their plants, and, in fact, some departments I was enabled to study for several days in succession. They took me in an automobile to drive around the plant, and it required the better part of the afternoon to run through the many streets of their plant and to visit hastily each of the many buildings." . . .

"There is another matter I want to call your attention to. The American promoter ordinarily wants to get rich quickly. He does not want to trust to any industry which requires slow but healthy development. A couple of years ago I spoke to the director of one of those large (German) enterprises, and he seemed pretty well imbued with the idea of the importance and development of his plant, and I asked him what dividends they paid. 'Oh,' he said, 'we are paying as much as 28 or 30 per cent dividends.' 'Well,' I said, 'that is a lot, but what does it amount to in dollars and cents?' Then he told me what it amounted to, and I was amazed at how little it was relatively speaking. I said, 'Have you any water in your capital stock?' 'No; that is not allowed in Germany.' 'Have you amortized any of your buildings?' 'Oh,' he replied, 'quite some.' I said, 'Then do you mean to say that your capital stock is considerably smaller than your real assets?' 'Yes,' he said. 'When did you start?' 'In 1862.' 'Do you mean to say,' I asked him, 'that after 50 years, that is all you have to show?' 'Yes,' he said; 'we are entirely satisfied.'

"Now, in America any third-rate industrial enterprise—badly managed as some of them are—at the end of 50 years would be ashamed to declare a dividend of that kind, if you calculate it on unwatered stock; but those people are satisfied with small profits. I know it, and I know furthermore—and probably Mr. Metz knows it, because he is a manufacturer, too—that some of their departments work at considerable losses. A large number of those departments do not pay at all. Some other departments pay better, and they equalize or offset the losses, and they seem to be satisfied with the ultimate result. But if you take those dividends and compare them with the dividends of some American concerns on the basis of their watered stock, their returns are disappointingly small from the American point of view.

"Gentlemen, there is one thing that you could do. I

have spoken of it to your chairman, and I wish to take the liberty of repeating it. If you really want to render any service to the industrial development of this country, and more particularly to its chemical industries; if you aim at any change in our patent laws, please arrange matters in such a way that patent litigation becomes more direct, less complicated, and less expensive. The way patent protection is now administered in our country is a gross absurdity, and no safeguard for chemical industries based on improvements and pioneering enterprises."

Mr. Metz said that the dyestuff imports into the United States are about $1,000,000 a month; $12,000,000 a year will cover all the importations of dyestuffs and raw materials for dyestuffs. "I want to emphasize that point as to the relatively small value of these things in proportion to the size of the industry into which they go—cotton, silk, wool, paper, typewriter ribbons. There is scarcely an industry that is not affected. Even the ink for the red headlines in the newspapers—those have had to be discontinued. The total new profit to the manufacturer of these materials (at a normal average profit of 25 per cent) would be at the maximum $250,000 a month, as compared with the entire business of the United States. If the German manufacturers shut down entirely they would lose almost nothing, but we would lose hundreds of millions of dollars for the lack of stuff to keep our mills going. That is why the Germans are not anxious to-day to export a single pound; it is a favor to us. They want to keep these things out of England. That is their business, if they want to do it. They do not want to let a single pound of these materials go to England or France or any manufacturing country, and they are afraid that if they give us any more we will send it to those countries. The trade in those products is a very small factor with Germany, and anything that will tend to prevent the importation of those things at this time will injure us to an extent that will far more than offset any benefit we will get."

Dr. Baekeland in concluding said: "I know that the importation of coal-tar dyes into this country—although it amounts to $12,000,000 a year—is a small item compared with a lot of other items of which we have not spoken at all. For instance, I know that New York City consumes in one year eggs of a value two and one-half times as great as the value of all the aniline dyes imported in one year into this country. Any man who could make a law to increase the size of eggs by one gram would make himself infinitely more useful to his country than a man who could increase the production of those aniline dyes. In fact, the trade in sheep manure for tanning and other purposes is about equivalent in value to the value of aniline dyes imported into this country."

The hearing was then adjourned.

The Engineering Foundation was inaugurated with appropriate exercises in the United Engineering Building, New York, on the evening of January 27, 1915, under the auspices of the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, the American Institute of Mining Engineers, and the American Society of Civil Engineers. A gift of $200,000 by Ambrose Swasey, designer and builder of the Lick, Yerkes and U. S. Naval Observatory telescopes, and an engineer, scientist and astronomer of high distinction, forms the basis of the Foundation. Mr. Swasey is a member of the firm of Warner & Swasey, machine tool builders, of Cleveland, Ohio, and a past president of the American Society of Mechanical Engineers. The principal speech of the inauguration exercises was made by Dr. Henry S. Pritchett. The fund will be used chiefly for research work.

Dinner to Frederick G. Cottrell

A dinner in honor of Dr. Frederick G. Cottrell was held on the evening of January 15 at the Plaza Hotel in New York City, under the auspices of the American Institute of Mining Engineers, the American Electrochemical Society, and the Mining and Metallurgical Society of America. The occasion was graced by the presence of many ladies.

The purpose of the dinner was to honor Dr. Cottrell for the service rendered by him to the advancement of science, as stated in the following minute, adopted on the same day at the annual meeting of the Research Corporation and distributed appropriately in printed form at the dinner:

"In 1911 Frederick G. Cottrell, B.S., Ph.D., offered to transfer to the Smithsonian Institution substantially all his rights in his inventions and patents covering the processes known as the electrical precipitation of suspended particles in order that the profits resulting from the application of the patents, already well assured, might be applied to the advancement of scientific research and investigation. Naturally this proposition was at once recognized as both generous in spirit and highly original in conception. It was Dr. Cottrell's ideal to render discovery already made the mother of new discovery, and thus contribute to the scientific and technical development of the industrial arts.

FREDERICK G. COTTRELL

"This far sighted and patriotic conception found its realization through the Research Corporation which for administrative reasons was substituted for the Smithsonian Institution as the custodian of Dr. Cottrell's endowment. The objects of the Research Corporation as stated in its charter are: 'To provide means for the advancement and extension of technical and scientific investigation, research and experimentation by contributing the net earnings of the corporation, over and above such sum or sums as may be reserved or retained and held as an endowment fund or working capital, to the Smithsonian Institution, and such other scientific and educational institutions and societies as the Board of Directors may from time to time select in order to enable such institutions and societies to conduct such investigations, research and experimentation.'

"Organized in 1912 as a stock corporation but precluded by its charter from paying dividends and capitalized by a group of gentlemen desirous of furthering Dr. Cottrell's objects, without personal profit, the Research Corporation undertook and successfully accomplished the installation of the Cottrell processes in various industries throughout the country, with the result that in two years' operation its surplus has provided the capital of twenty thousand dollars required by its charter, and a fund of over one hundred thousand dollars for scientific research.

"The accomplishment of this remarkable result, which both justifies Dr. Cottrell's expectations and realizes his hopes, is due to his generosity and foresight, and the

PHOTOGRAPH TAKEN AT DINNER TO DR. FREDERICK G. COTTRELL

Directors of the Research Corporation take this occasion to express to Dr. Cottrell their appreciation of his contribution to scientific achievement and to the advancement of science, and tender him their cordial congratulations and sincere thanks for the public service which he has rendered."

Mr. SIDNEY J. JENNINGS presided at the dinner. In his introductory remarks he spoke of mining as the basis of civilization and of Dr. Cottrell as a very practical idealist. He proposed a toast to Mrs. F. G. Cottrell, who had been compelled to stay in California and could not witness the tribute of esteem and affection paid to her husband.

Dr. CHARLES D. WOLCOTT, director of the Smithsonian Institution, spoke for the Research Corporation. He related how Dr. Holmes had brought Dr. Cottrell to him and how the organization of the Research Corporation finally resulted. He spoke of the many practical problems which are being taken up or are to be taken up by the Research Corporation, and of Dr. Cottrell's idealism.

Mr. WILLIAM L. SAUNDERS then spoke for the American Institute of Mining Engineers. He said his experience with inventors had been as extensive as it had been expensive. One of the directors of the Research Corporation had told him that the Cottrell patent was worth one million dollars. "This is not at all an unfamiliar statement about a patent to me, though the novelty of it is that heretofore I have heard it only from the inventor. An inventor with a patent, whether it relates to a clothes pin or a submarine, invariably rates its value at one million." Mr. Saunders related forcibly a wonderful story of a dynamite inventor with a patent alleged to be worth a million. The story was fearsome, but had a happy ending. Mr. Saunders concluded:

"But the controlling thought with all of us to-night—the impulse which has drawn us together—is not that we wish to do honor to a great inventor, but to the man. Ours is not a compliment to the brain, but to the heart. That which we so regard, that to which we pay the homage of our admiration and cheers is that one of our kind should be so unselfish as to dedicate this valuable product of his brain to the public good. In doing this he has not only rendered a great service to mankind, but he has set a wholesome example to present and future generations.

"The governor of a western state, who was also a member of the board of directors of a railroad company, told me the following story: He was presiding over the annual meeting of the directors in a western town when a man opened the door of the room and after politely apologizing for the intrusion asked for a few moments' attention that he might explain his plan by which a large sum of money would annually be saved to the railroad company. The first impulse was to put him out, but he held his ground by the statement that as the directors were there for the purpose of saving money for the company, and he stood ready to help them, they should at least let him explain his business. He then said that he had a patent oil for railroad use, the virtues of which he was diligently expounding when the superintendent entered the room in response to a bell call and was ordered to give the patent oil a trial.

"On the year following, these directors met at the same place and recalling the incident the chairman asked the superintendent what was the result of the trial of the patent oil. 'All right,' said the superintendent. 'It is a satisfactory lubricant.' 'Well, I'm glad to hear that,' said the governor; 'the interruption at our meeting last year was a good thing after all; that fellow must have a valuable patent.' 'Governor,' the superintendent replied, 'the value of that patent *is that man.*'

"And so it is in this case, for the economic worth of Professor Cottrell's invention, as high as we know it to be, cannot equal that real value of the patent which is that man. The man whom we so gladly and so unanimously honor this evening is deserving of our highest esteem, for 'hearing ofttimes the still, sad music of humanity,' he is built of such stuff, that,

> "Too high for common selfishness, he could
> At times resign his own for other's good."

Mr. F. AUSTIN LIDBURY followed, speaking for the American Electrochemical Society. He gave reminiscences of the time when he worked alongside Dr. Cottrell at Ostwald's laboratory in Leipzig, "a pleasure which those who shared it will not easily forget."

"Added to those personal qualities which have since won him a nation-wide circle of friends and admirers, we had the advantage of associating with one whose bold and brilliant ideas were only equalled by his ingenuity in devising and executing experiments to test those ideas. He was the most brilliant and original experimenter that I had ever met, and he used to startle us every day or two by producing some new marvel of experimental ingenuity. If he will permit me to say so, I must confess that if the first experiment did not work, it was rarely followed by a second one; but this was no doubt attributable to the fact that he came to us fresh from Van't Hoff's laboratory, where one was held pretty closely down to the determination of vapor tensions and solubilities; no doubt very excellent training, but rather calculated to arouse unruly thoughts in an ardent mind.

"I am asked to speak of Dr. Cottrell's work on electrostatic precipitation. Of the results and far-reaching importance of that work it would be presumptuous on my part to speak to this audience. Nor am I capable of describing adequately the quality of the work itself, or its importance. There are two points to which I would direct your attention.

The first is, that when Dr. Cottrell undertook his investigations the prospects were sufficiently discouraging.

"Electrostatic precipitation of solid particles from gases was no new idea; in particular, it had been experimented with by a famous English physicist, who had, however, not even succeeded in dispelling the fog in his own quadrangle. It did not look either to a scientist or to an engineer exactly the kind of thing that one calls 'practical.' Companies to whom the removal of noxious fumes from gases was a vital matter were not inclined to give the idea when presented to them very much consideration; it was altogether too good to be true; and while money might easily have been found for a small improvement which might look as though it would save a few thousand dollars a year in some detail of their properties, this was altogether too vital and too important a matter to spend money on.

"Under these circumstances, Dr. Cottrell simply went and did it. That is all there is to say in this connection.

"The second point is one which particularly concerns the electrochemist. At this moment, when the revolutionary electrochemical activities of the last decade but one have settled down into a kind of steady development, Dr. Cottrell's success comes as an inspiration to the electrochemist. It indicates to him that the large successes of electrochemistry in the future, the untilled field, are to be sought among the byways and hedges of that bastard technical science.

"But we have met to-night to recognize also Dr. Cottrell's eminent services as an experimentalist in social science. That he so regards himself is abundantly clear from the very interesting paper on the Research Corporation which he presented at the last International Congress of Applied Chemistry. I know few more interesting papers than this, and not its least interest lies in the fact that it is to a great extent a human document. No one, I think, can read this paper without being impressed by the extent to which it reveals that modesty which is one of Dr. Cottrell's chief characteristics.

"Now the particular branch of social science in which Dr. Cottrell has interested himself is that which embodies the relations between the universities and the technical industries. I doubt whether any more fruitful subject for discussion than this has been before scientific people in the last few years. One is reminded of the old Scotchman who was visited by his minister when he was lying on his death bed. 'Sandy,' the minister said, 'shall I read ye a little from the good book?' 'Nay, nay, meenister,' said Sandy, 'sit ye down and let's argue a wie.' Certainly there has been enough argument on this question. Most diverse positions have been assumed; the head of one of the largest research laboratories in this country has been bold enough to state that the time has now arrived when the universities must yield research to large technical industrial organizations, just as centuries ago the church yielded research to the universities. My friend's boldness was, however, tempered with discretion, as he published his article at a time when those who might be expected to be interested in combative issues were taking their vacations.

"Dr. Cottrell stands emphatically on the other side of the question, and his notable contribution is that while, with practically one other exception, the parties to the discussion have confined themselves to discussing, he has gone at the matter in an experimental way. And not only so; experimental research is expensive; and Dr. Cottrell has put at the service of the experimental work on this social question what would have been a most munificent gift from any man on earth; and what, coming from one who is a poor man, is only to be described as unparalleled. Only a scientist in the truest and rarest sense of the word would be capable of such generosity or such self-sacrifice. He has made an indescribable sacrifice in order to try out on an enormous scale the social idea.

"It only remains for me now to wish the Research Corporation every success. Its responsibility is commensurate with the generosity of Dr. Cottrell's gift. It will not find other Cottrells—they do not grow on every bush."

Mr. WALTER RENTON INGALLS spoke for the Mining and Metallurgical Society of America. He mentioned that Dr. Cottrell's official title is that of chief physical-chemist of the U. S. Bureau of Mines.

"If any here present this evening may not happen to know just what a physical chemist is, they need experience no mortification or entertain any notion that their early education was neglected. The physical chemist is, indeed, a rare bird of a new species. Those of us who possess sheepskins dated in the early eighties and in the middle eighties, pursued courses in chemistry and courses in physics, but at that time it had not occurred to anybody that we ought to study the two together. This did not happen until later, and for the reason that the older chemists and metallurgists were not taught the rudiments in the right way they have always been at a disadvantage compared with those of the younger generations, no matter how seriously they have tried to correct the deficiency.

"We are very much like a coachman who was converted into a chauffeur. In the early days of the automobile the chauffeurs as a class possessed a very bad reputation, which no doubt they richly deserved. A certain gentleman, desiring to avoid the evils of grafting, joy-riding, etc., conceived the idea of making a chauffeur out of his honest, reliable and intelligent coachman, and for that purpose sent him to an automobile school of instruction. After three months or so, James returned proudly exhibiting his diploma. 'Yes, sir,' said he, 'I have learned all about the automobile. I know how to put in the gasoline and how to put in the oil. I know how to adjust the carbureter and how to clean the spark plugs, and how to scrape the carbon from the cylinders.' Then waxing confidential, he added, 'Yes, sir, I know all about the automobile engine, but there is one thing I have never been able quite to get into my head, and that is, what makes the blame thing go?'

"Many of us are in the same position with respect to chemical reactions and metallurgical processes in the light of modern theory. We have learned how to pull some of the levers and press some of the buttons, and make things go, but why they go we do not always understand as well as we ought to. We are apt to be strong upon the means how, but weak about the reasons why. Therefore, we sit at the feet of the masters of physical chemistry, among whom is Dr. Cottrell—the modern science in which is wrapped the whole future of metallurgy.

"Now, even before physical chemistry became a science we smelters of an olden time were having our experiences with the gentle art of smoke farming. We were all quite familiar with the agriculturist of our neighborhood who, from time to time, used to call at our works and complain that our sulphur smoke had damaged some especially promising field of corn; or that old Dobbin had developed a spavin, which was probably due to our sulphur smoke; or that the chickens had fallen sick of the pip, for which our sulphur smoke again was to blame. We used to sympathize with our bucolic friend, and wonder whether $50 might compensate for damages, assuage injured feelings, etc. Generally, they allowed that it would, and disappeared for six months, a year, or whatever time they considered to be a proper interval between contributions.

"But as our smelting works became larger and more profitable, so did the avarice and aspirations of the smoke farmers increase, until at length their demands became so onerous that no smelter could agree to them and hope to continue solvent. The consequences were suits for damages, court injunctions, and the development of smelters' smoke as one of the great metallurgical questions of the day, engaging the attention of scientists all over the world. Among these was Dr. Cottrell.

"Dr. Cottrell was acquainted with the experiments of a distinguished British scientist. to whom Mr. Lidbury has already referred, for the settling of London fogs by electrical means. Those experiments had, however, resulted in nothing useful, and the idea of electrical precipitation had been generally dismissed as fruitless. But not so by Cottrell. It was on the point of my tongue to say that Cottrell was from Missouri, but I have happened to remember that in fact he is from California, and anyhow I have never taken much stock in the quality commonly ascribed to Missourians of sticking fast to the idea that seeing is believing. Tell a Missourian that in the firmament above us there are three trillion, several billions, millions and thousands and three hundred and sixty-seven stars and he will believe you without question, just as will a Hoosier or a Yankee. But show a Missourian a place marked 'wet paint' and he will immediately try it with his finger. In fact, human nature is about the same everywhere.

"Well, anyway, Dr. Cottrell prosecuted his investigations, made his inventions, and proved his theory to be correct, and in a surprisingly short period of time we have seen his process attain great importance in our metallurgical industry. And, not only in that, but also has it found applications in other industries. Dr. Walcott has mentioned some of these. It is used for allaying the troublesome dust in cement works. It is used in the preparation of certain powdered foods, especially powdered milk and powdered eggs. It is possible that some of the delicious confections that we have eaten here this evening were prepared by the baker of this hotel with the aid of Cottrell powdered eggs. If not, I submit that the dinner committee should have seen to it. Surely, there is no one here who would not have taken such a chance—once.

"I understand that Dr. Cottrell, not satisfied with the

accomplishments that already are remarkable, is contemplating other Romes to conquer. I believe that he entertains serious ideas of abolisning the smoke of Pittsburgh. If he succeeds in doing that, I do not venture to prophesy the size of the monument that Pittsburghers will erect to him at the junction of the Allegheny and Monongahela rivers.

"Professor Cottrell munificently gave away his process in the interest of science. Mr. Saunders has told us that this process, even in its kindergarten days, is considered to be worth a million dollars. There are not many men who would give away anything worth a million dollars. But we know that Professor Cottrell, besides being a genial and generous gentleman, is a good deal of a philosopher. The path of the inventor, even of the successful inventor, is seldom a smooth one. It may be that Professor Cottrell's philosophy taught him that it is better to be honored and healthy than worried and wealthy. We have tried this evening to show him somewhat of the esteem that we have for him."

The health of Dr. Cottrell was then proposed.

Dr. F. G. Cottrell gave a very fine personal touch to his speech by making the co-operation given to him by others the keynote of his remarks. He insisted that his colleagues in the old Western and International

FROM LEFT TO RIGHT: STANDING, E. O'NEILL, F. G. COTTRELL; SEATED, E. S. HELLER, H. E. MILLER

Precipitation Company should be named with him as co-donors of the patents to the Research Corporation. The first to assist him had been Dr. Harry East Miller, to whose private laboratory in San Francisco the experimental work had been transferred at an early date after it had been started at the University of California in Berkeley on a small scale. The earthquake and fire of 1906 finished this early work. Then Mr. E. F. Heller, a lawyer and business man of San Francisco stepped in, and Professor Edmond O'Neill of the College of Chemistry, of the University of California, became the fourth member of the coterie which carried on the pioneer work for five years until it was turned over to the Research Corporation.

Dr. Cottrell spoke of the help extended to him by Dr. Holmes, Dean Goetze, and others, of the late Dr. Duncan's idealism which resulted in the Mellon Institute for Industrial Research in Pittsburgh, of the international character of scientific organization, and finally paid a quiet and beautiful tribute to the help he had received in all his work from his wife, who had remained in the little bungalow in California while he had gone East on this trip. "You don't know a man until you know his wife."

Annual Report of the Bureau of Mines

In the fourth annual report of Dr. Joseph A. Holmes, director of the federal Bureau of Mines, he presents a summary of the work of the Bureau during the last fiscal year ended June 30, 1914, and discusses some of its needs. An interesting tabulation is made showing the country's relation to the two great basic industries, mining and agriculture, and the federal support given each. The salient facts are that agriculture shows an annual value of products $10,500,000,000 as against $4,600,000,000 for mining; but mining contributes 60 per cent of the freight tonnage of the country as against 22 per cent for agriculture. On the other hand, agriculture receives annually from the government for education, experiment stations and general research $27,970,000, as against $1,967,000. Agriculture is aided by 52 experiment stations for which $1,550,000 is appropriated, while mining receives no appropriation for such work. Bearing on the latter point, and in supporting the idea of mining experiment stations, the Director says:

"Owing to the magnitude of the country, the distances between the widely distributed mineral regions, and the marked differences not only in the nature of the mineral resources of this country, but also in the conditions under which they must be developed, it does not appear to be practicable to conduct efficiently at any one central point researches concerning all of these mineral resources. In addition to one or more central control laboratories, it is important that there should be established in a number of the more important mineral regions of the country local mining experiment stations at which researches may be conducted in keeping with the nature, mode of occurrence, and the development of these resources.

"There should be not less than 10, and probably need not be more than 15, such stations established, the larger number of which should be located in the public-land States west of the Mississippi River. These 15 mining experiment stations will do for the mining industry in this country a work comparable in importance to the work which is being done in behalf of agricultural advancement by the 52 agricultural experiment stations, for the maintenance of which Congress appropriates annually more than one and one-half million dollars, or $30,000 for each station.

"It is expected that the work of each of these mining experiment stations will be supplemented through appropriations made by each of the mining States in which such stations are to be located, and it is further expected that the appropriations made by the States will provide for such portion of the investigations as are local in their character and importance, whereas the investigations provided for out of the appropriations made by the Federal Government will be of a general or national character and importance.

"It is proposed that the establishment of these stations should be provided for through the enactment of special legislation which is now pending before both branches of Congress (H. R. 15869 and S. 5588). The importance of this legislation to the mining industry is such that it can hardly fail of enactment, and with its enactment the bureau will be able to take up and carry to successful completion researches which cannot fail to be widely useful in the upbuilding of the industry."

Leaching of Copper Ores and Electrolytic Precipitation was the subject of a spirited discussion, opened by a paper by Dr. L. D. Ricketts, at a joint meeting of the New York Sections of the American Institute of Mining Engineers and the American Electrochemical Society on January 6. A report is reserved for our next issue.

Handling Iron and Cinder at the Blast Furnace

BY J. E. JOHNSON, JR.

(*Concluded from page* 50)

Handling the Slag

When the blast furnace had its beginning it is almost certain that the slag was handled as clinker or ashes, and this point of view survived until very recent times in the crane-operated shovel, fork, etc., which I have described in a previous article as adjuncts to charcoal furnaces in the seventies and which were used to clean out and "work down" the furnace very much as we find it necessary to do with the average domestic heater to-day. The difficulties of this method of operation a growing knowledge of the use of flux, and the use of the

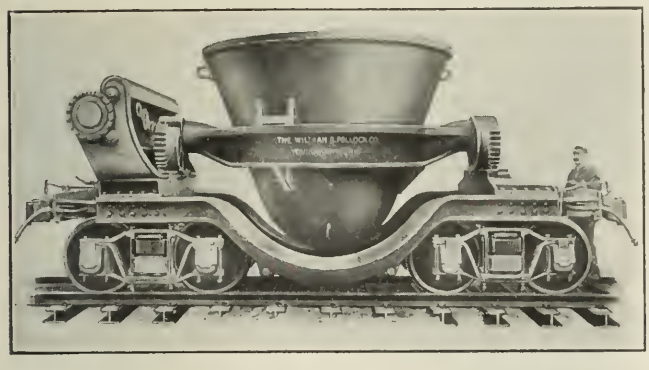

FIG. 15—POLLOCK CINDER LADLE

hot blast with its correspondingly higher hearth temperatures brought the possibility of discharging the slag in the liquid condition and this practice became general though not universal in the early part of the last half of the nineteenth century.

The slag was probably allowed to run out from the furnace with the iron, and after being skimmed off as previously described, was run off to a short distance into puddles in which it was allowed to cool. Slag being very brittle when cold is easily broken up by hand and was disposed of with carts or any convenient means, being simply loaded from the ground into the conveyance with shovels or forks. Carts dumped it into holes or low places, and sufficient of these were commonly found near the plant to take care of the slag output for many years.

Survivals of this method are in use even down to the present time, though they have now become rather rare. When mineral coal was substituted for charcoal as fuel, the quantity of slag produced per ton of iron increased to some extent, but probably not nearly in the ratio which the average volume of charcoal slag bears to that of coke slag per ton of iron produced to-day for the reason that in the early days of mineral fuel it was almost impossible to carry as much lime in proportion to the silica of the charge as we now know how to handle successfully. But even though the difference was not so great it was still very considerable and helped to bring about a change in the method of handling, because with small outputs of iron, and small ratios of cinder per ton of iron, the volume of this material to be disposed of was so slight that no highly organized methods were used for disposing of it.

But with the increase in volume of slag, and also the great increase in tonnage of iron, the importance of slag disposal grew even more rapidly than the question of handling the pig iron output, and a vast number of methods have been devised and practiced in trying to handle it with maximum economy.

A comprehensive search would be required to obtain a reasonably complete list of the methods which have been used on an industrial scale in the past, but as only a few of them have survived this is not needed, a description of a few of the most commonly used will suffice.

The first important development was the choice of a definite dumping place, chosen with the idea of affording room for slag disposal within a limited area for a long term of years and railroad transportation for delivering the slag to it.

Probably the earliest improvement was to run the cinder into long parallel runners roughly made up in coke brise so that the size of the individual bodies of cinder is limited, because while this material is very brittle as compared with iron, if it is cast into puddles of several feet across, and a foot or two thick, it cools very slowly, and this slow cooling anneals and greatly toughens it, so the difficulty of breaking it up grows very greatly with the size of the body into which it is cast.

When cast in long runners of approximately semicircular shape, a foot across, and six inches thick, it was handled with hooks, one in the hands of each of a pair of men, who broke the runner of cinder up into pieces, three or four feet long, and swung it onto a pile by catching it with a hook near each end. The sections of runner were piled roughly together and allowed to cool still further, after which they were loaded onto

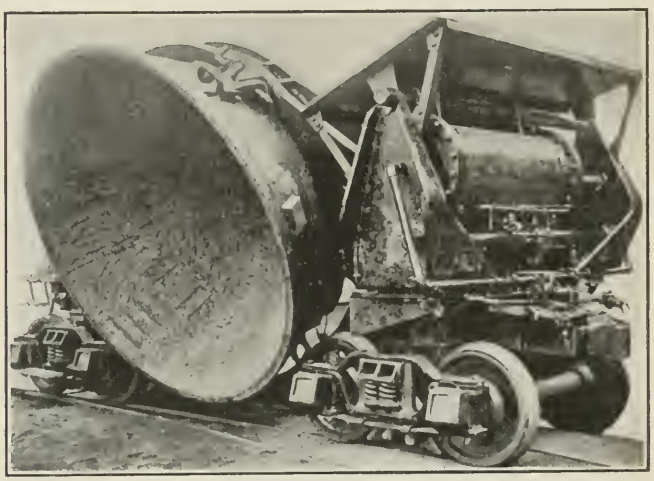

FIG. 16—TREADWELL CINDER LADLE

cars and taken away. This cleared the beds for the next fall of cinder.

In other cases quite large holes, approximately round, were dug into the ground, the cinder allowed to run into these, and a bar or hook of iron stuck into the center while it was still hot. After the cinder had hardened it was picked up by this hook, with the aid of a crane, and loaded for disposal. At the dump the cake was broken up and the hook or bar of iron recovered to be used again.

In other cases the cinder was cast into cakes on cars made entirely of iron, which had a perfectly flat top, so hinged to the body of the car that it could be tipped laterally in either direction. On top of these were set cast iron frames, the section of a truncated pyramid with the sides sloping inward at the top, and without top or bottom. A joint between these and the deck of the car was made with brise or fine cinder, and they were run full of cinder direct from the cinder trough at the furnace. After cooling the iron frames or molds were lifted off with a crane, the train of cars taken to the cinder dump, and the decks tipped, allowing the cakes to slide off over the dump. In this case of

course, as with practically all dumps, the tracks must be moved either laterally or built ahead as the dumping space is used up.

About thirty years ago the practice of handling the slag in the liquid condition began to receive quite general recognition, and has developed continuously and rapidly from that time. The first liquid cinder cars were simply huge rectangular tanks of steel plate, lined with firebrick, mounted on trucks, with a spout closed by a hinged gate at each side. The gate was closed, a little cold cinder thrown against it, and the tank was then filled with liquid cinder and hauled away, At the dump the gate was swung aside and the chilled cinder over the opening broken through, and the contents of the car then ran out. But this method was open to serious objection because even when very quickly handled slag forms quite a heavy skull under such conditions, and this skull fastening itself to the brick-work grows with each successive filling and emptying of the car until the capacity is so diminished that it must be cleaned out by hand, a laborious and time consuming operation. If the car were allowed to stand until the cinder froze on top it made matters still worse as this additional skull also had eventually to be handled by hand.

To eliminate these difficulties cars which dumped their contents by tipping bodily over were developed. These also were at first made of steel plate lined with firebrick, but even when emptied by tipping over they skulled up quite rapidly, and it was finally found that cast iron pots could be successfully used, and that being smooth inside the skull freed itself from them very much more readily than from the brick. These at first were made of the same shape as the steel plate ones had been, with almost straight sides, and flat bottom which gives maximum capacity, but it was found that by increasing the taper of the sides the pots could be made not only to dump cleaner, but to throw out the skull in the dumping position without barring or hand cleaning. Consequently such pots are now universally made with so heavy a taper that they are almost true cones, having only a small spherical bottom.

The design of the William B. Pollock Company is shown by Fig. 15 and that of the Treadwell Engineering Company by Fig. 16. Much ingenuity has been expended in devising the best mechanism for controlling the movement of these pots and dumping them with the least labor. After they had been in use for some years with the dumping gears driven entirely by hand, Mr. Samuel Stewart, then master mechanic of the Woodward Iron Company at Birmingham, Ala., patented a successful design in which a steam cylinder mounted on the car and connected to the locomotive, supplied the power for dumping and restoring the pots to their normal position without any labor and in much less time than was required for the hand-operated pots. This idea has now been applied universally to these pots, but with the very general equipment of locomotives with compressed air for brakes air is used to operate the cylinders instead of steam. With this device a whole train of these cars can be tipped, emptied, the skulls thrown out, and the cars restored to normal position, in a period measured only by seconds.

By the use of these side dump pots the dump may be built up approximately to track level on the dumping side so that the tracks can be moved over with but little labor, when the drop from the cars is no longer sufficient to free them properly, but cars of this type do not permit dumps to be carried ahead except by the laborious method of building up the dump at the end of the track by hand filling.

In order to make room as fast as it is used up, it is generally very desirable to build a track ahead, and for this purpose other types of cars have been devised. The earliest of these was the design of the late John M. Hartman. It consists of a half cylinder of steel plate lined with firebrick, with an extension around the top of cast iron plates, one side of the cylinder being flared out to make a pouring lip and the other side built up vertical. This half cylinder rests on a four-wheeled truck, to which it is fastened by two pairs of chains, one with the front end fastened to the cylinder and the back end to the truck, the other with the back end fastened to the cylinder and the front end to the truck, one pair of these being on each side. These act practically like a rack and pinion and leave the cylinder free to roll on the truck without the possibility of being displaced endwise by sliding; it is guided laterally by angle iron half rings riveted to the cylindrical surface, which work between guides on the truck.

These cars are not coupled directly to the locomotive but by means of a push pole sixteen to twenty feet long. After filling at the furnace these cars are taken to the end of the dump, the truck locked fast on the track with a powerful brake or "scotched," the locking mechanism of the body released and the half cylinder pushed over by the locomotive operating through the push pole which is fastened to the car with a swivel coupling.

The disadvantage of end-dump cars is of course that only one can be dumped at a trip, and if several have to be handled as many tracks must be provided as there are cars, or nearly so, because the heat at the end of the dump is too great to permit dumping one car

FIG. 17—BROWN HOIST CRANE LOADING CINDERS FROM PIT ONTO RAILROAD CARS

immediately after another, and of course a separate switching operation is required for each car dumped, in fact two of them when more than one ladle car is used, one switch to dump the car and set it out, another to pick it up and take it back.

It is a curious fact that these cars build a dump which is almost precipitous in its slope, both on its sides and on the front. A "fill" can be constructed from them with great economy of material because its sides are almost vertical.

On the other hand, the side dumped cars produced very flat slopes. As little as ten or fifteen degrees suffices to carry the slag away from the track with this type of car.

Another type of end dump car with a round "thimble" like that of the side dump car is made by the Treadwell Engineering Company and works with a similar mechanism, but fore and aft instead of laterally. It is of course a more difficult design because the truck is in the way

of a free end-dump, but this difficulty has been successfully overcome.

How a slag dump is to be handled is very largely a matter of local conditions, but I have always felt that the benefits of the end dumped car for building ahead

FIG. 18—BROWN HOIST TRAVELING CRANE AND GRAB BUCKET FOR HANDLING CINDERS

were not properly appreciated, and that the ideal combination would be two or three, or even four or five side dump pots with an end dump pot on the front. With this arrangement all could be dumped simultaneously without switching, and the end-dump pot would build ahead about as fast as the side-dump pots used up the track room it provided.

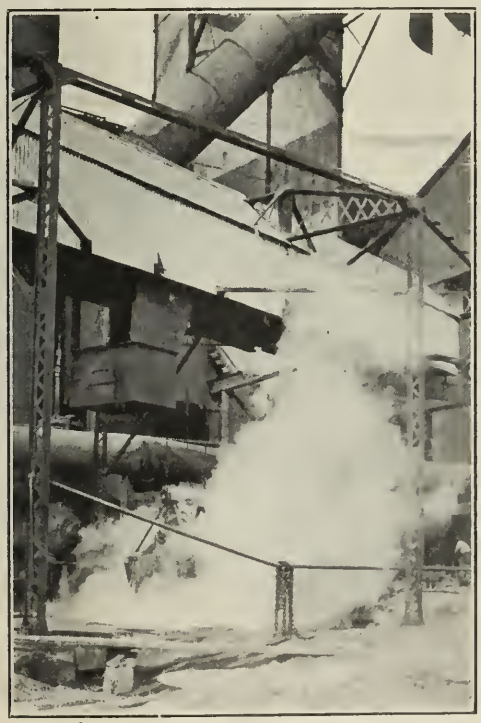

FIG. 19—BROWNING GRAB BUCKET RISING OUT OF PIT WATER DRAINING OFF

The "hot pot" method of handling slag is economical for a large plant of furnaces, and where dumping room is available within a reasonable distance; but in congested districts where the only available land between high bluffs and a river is a narrow strip of bottom, every inch of which is necessary for plant and railroad tracks, it is not always easy to find a place in which to dispose of the slag without a long chance that one will be exceedingly sorry for having put it there later on. Of course if a river or harbor can be filled to the harbor line this makes an ideal condition, but one which will not last indefinitely. Moreover, this method of handling slag requires a locomotive and crew in absolutely constant attendance day and night, Sundays and holidays. If the cinder cars get off the track, which not infrequently happens on the rough tracks on the dump, and the cinder train is blocked, the furnace may be put to desperate straits before the situation is relieved by the return of the cinder cars. The expense of the locomotive and crew is just as great for a single furnace as it is for three or four, and the cost of slag disposal per ton of iron produced is therefore very much heavier by this method in small plants than in large ones.

Granulation

These difficulties have prevented the universal adoption of this means of slag disposal, and have caused the development of others, of which by far the most important is "granulation." This was first practiced in this country, so far as known to me, by Captain T. C. Jones, I think, at a small blast furnace near Lynchburg, Va., and was subsequently applied by him, and still continues in use, at a furnace at Iron Gate, Va., where the slag is flushed directly into the James River and carried away by the current of that stream. The method consists in running the cinder out through a trough with a projecting end, just beneath which is placed a flat jet or nozzle about the same width as the trough. When the cinder starts to run a powerful current of water is turned into this nozzle, and the cinder running from the end of the trough falls onto this jet whose velocity is sufficient to tear the cinder into small shot as it runs, and these, of course, are prevented from recementing by the chilling action of the water.

FIG. 20—BROWNING GRAB BUCKET OPEN OVER PIT

Most plants which use this method of slag disposal are not so located that they can flush the cinder directly into a river, and these have installed a huge concrete lined pit or tank sunk in the ground, into which the cinder and water from the jet fall together, and from which the cinder is recovered, generally by means of a clam shell bucket, and loaded onto cars. It is by that time cold so that there is no danger of fire; the cinder

is between course sand and fine gravel in size, generally rounded, and a very easy material to handle. It of course may be carried any distance desired to make fills on railroads, or the like, since the time element does not enter into its disposal as it does when handled liquid, and it can be handled virtually without expense in outward bound empty cars, and has in the past been very generally handled in this way by the railroads, without charge on account of its value to them as a filling material.

The clam shell bucket for recovering the cinder from the pit is operated in various ways, either by an overhead crane, a crane trolley without lateral movement, or by a locomotive crane running on a standard or broad-gage track. An arrangement of the latter kind may be seen in Fig. 17, which shows a Brown Hoisting Machinery Company crane engaged in this service. The pit cannot be seen, but its position can be judged from the ropes running from the end of the boom down to the clam shell which is out of sight in the pit, also

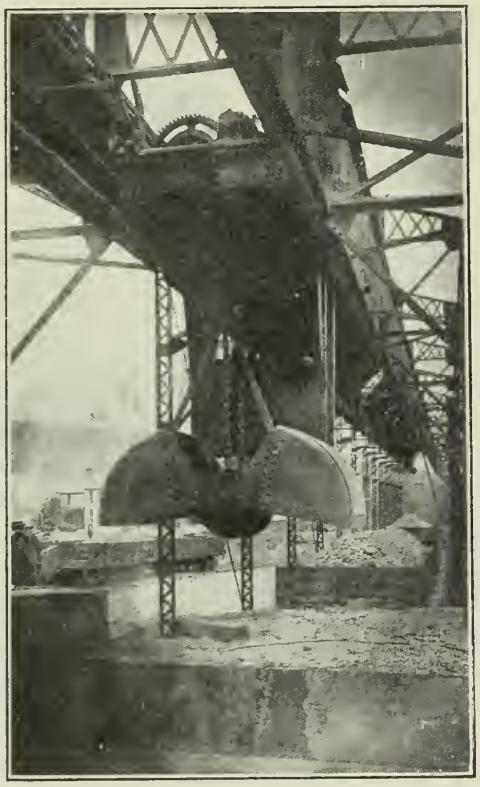

FIG. 21—BROWNING GRAB BUCKET OPEN OVER PIT

by the steam rising from it. The granulated cinder is raised out of this pit and swung over into the hopper cars from which steam is seen rising on the right hand side of the picture.

Fig. 18 is a view of the same plant and crane from a different position. The pit may be distinguished by the steam rising from it at the extreme left of the picture, while the white granulated slag in the car showing just under the crane boom is plainly visible.

Fig. 19 shows a clam shell operated from a trolley on an overhead runway, installed by Victor R. Browning & Company of Cleveland. The clam shell just at the top of the pit may be clearly seen with the water contained in the slag running from it. The clam shell open, dropping into the pit, is more plainly shown by Fig. 20. In this the perforations in the bucket for allowing the water to run off are plainly visible. The clam shell in its open position with the cars of loaded slag under the runway, are clearly shown by Fig. 21.

A different design by the same company of the same general arrangement is shown by Fig. 22

The trolley for handling the bucket with its mechanism and the operator's cage are shown by Fig. 23.

This method of handling slag has the great advantage that it gives several hours leeway, since slag can be stored in the pit without requiring to be removed for a

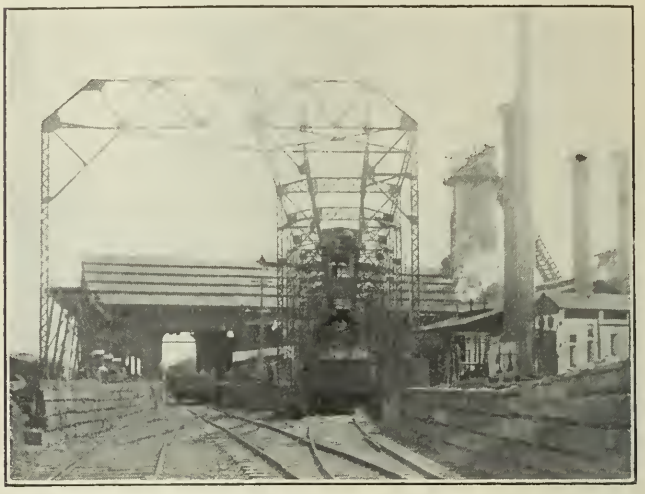

FIG. 22—BROWNING CRANEWAY WITH TROLLEY AND GRAB BUCKET

considerable period, so that breakdowns of the slag handling apparatus may occur without necessitating the shutting down of the furnace.

By providing a pit a little larger than common it would be very easy to store the slag for twelve hours or more, and so eliminate the operation of the slag trolley on one shift. Where the railroads take the slag, and the shifting engine is available for handling empty and loaded cars, this method is more economical for a single or even for a two-furnace plant than the liquid cinder method because it can be run by a single oper-

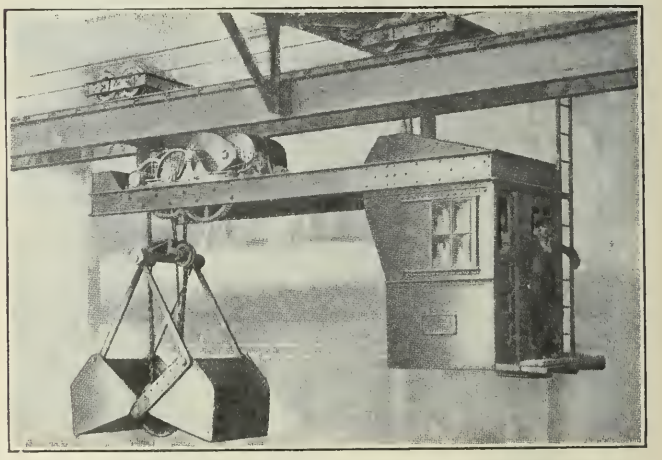

FIG. 23—BROWNING MAN-TROLLEY AND GRAB BUCKET

ator, whereas the other requires a locomotive and crew of two shifts as before stated.

Casting the Cinder and Handling It Cold

In recent years, since the very general introduction of concrete, it has been realized that slag allowed to cool slowly made one of the best aggregates that could be found, much better than limestone, because being of igneous origin it does not break up under the action of heat, as limestone has been known to do in case of fire.

Cinder is exceedingly rough and therefore furnishes an excellent bond for the cement, and in general cinder concrete is very highly esteemed by those who have used it.

Cinder is often recovered for concreting and road filling purposes by blasting the dumps made by ladle cars and loading them up with a steam shovel, but the cinder has generally run out in thin sheets which do not weld together, so that the mass breaks up into quite small pieces when it is reloaded. Moreover, this process requires the double operation of removing the cinder in pots and then picking it up with the steam shovel.

Mr. D. T. Croxton, of the Cleveland Furnace Company, some years ago, initiated the plan of casting the cinder directly from furnace in the old-fashioned way, but handling it by mechanical means after it was cold, crushing, screening and selling it for concrete material.

After a course of development for several years in which he installed a considerable quantity of special machinery, he finally came down to the simple practice of bedding heavy chains into the cinder bed before casting the cinder into it, these chains being covered up so as to prevent the slag from burning them. The slag bed is served by an overhead crane which takes hold of the ends of the chains at the sides of the bed and pulls them up through it. These chains are spaced a few feet apart and this breaks the slag bed into a material which can readily be picked up by a modern clam-shell bucket and loaded into cars for delivery to the crushing and screening plant.

This system without the mechanical equipment for handling the slag has been in use at other places where the slag has a commercial value as filling or building material.

One considerable advantage of handling the slag in this way is that a magnetic separator can be introduced into the path of the crushed slag and used to recover from it a considerable quantity of iron in pieces from the size of a pin head up to several pounds weight. This is true even with good furnace practice and where no important quantity of iron is visible to the eye, since the iron is so much heavier than the cinder that it goes to the bottom and is covered over by the latter.

It has been the experience of almost everyone who made any attempt to recover iron from the slag to find more than was expected when the attempt was begun. I myself had once the pleasant experience of putting in a magnetic separator in the hope of recovering four or five tons a month from a charcoal furnace, and actually recovered fifteen to twenty-five.

Many other methods of handling cinder have doubtless been used and perhaps a considerable number of these are still in operation, but the ones here described cover all the important methods in use on a large industrial scale.

The sampling and analysis of coal is treated at some length in *Technical Paper* 76 of the U. S. Bureau of Mines. Methods of sampling and analysis and interpretation of results are given in detail.

The Electric Furnace in Metallurgical Work is the title of *Bulletin* 77 of the U. S. Bureau of Mines. It is a compilation of data and useful information for the use of persons interested in the subject. Part I, by D. A. Lyon and J. F. Cullen, is devoted to the design, construction and operation of electric furnaces; part II to the smelting of metals in the electric furnace, by D. A. Lyon and R. M. Keeney; and part III to the manufacture of ferro-alloys in the electric furnace by R. M. Keeney.

The Arizona Copper Co. produced 1201 tons of copper during December, 1914.

Tube-Milling for the Flotation or Oil-Concentration Process

BY W. B. EASTON

In the December number of *Metallurgical & Chemical Engineering* there is an interesting article by Mr. W. J. Pentland, entitled "Notes on Tube-Milling in All-Slime Cyanide Practice." Under heading, "Duty of Tube Mill," Mr. Pentland questions the use of the tube-mill in closed circuit as being the most efficient method of using that machine. In regard to this phase of tube-mill practice, one hears the statement so frequently nowadays by engineers and millmen generally, that *"the most efficient machine is the one which keeps the greatest quantity of pulp in closed circuit,"* that I had nearly ceased to consider it as a debatable question. However, this statement may be no more axiomatic than the one that "the proper percentage of moisture for tube-mill feed is 38 per cent."

During the summer and early fall of 1914, I spent three months daily watching the operation of a 72″ x 20′ tube-mill. This tube-mill was fitted with the Chalmers & Williams patented adjustable quick discharge, and was running on split feed with conical tube-mills crushing copper ores for the flotation or oil-concentration process.

It is not the purpose of this article to make comparisons of the work of the two types of machines, but to use the results of some of the observations made during this time to throw some light on the question of the desirability of operating a tube-mill in closed circuit with a classifier, in order to obtain the highest efficiency from the tube-mill; and, incidentally, to show that with this type of tube-mill at least, there is no law which makes it necessary for the tube-mill feed to contain 38 per cent of moisture, for the percentage of moisture in the feed varied from so dilute a pulp as two parts of water to one part of ore, to only 29 or 30 per cent moisture.

The tube-mill under observation was used to prepare ore for treatment by the oil-flotation process for recovering the mineral; but the same conditions which would make the mill most efficient for this work would also make it most efficient for preparing ore for treatment by cyanide or, in fact, any subsequent process. It was decided, in order to get the best results from the oil-flotation process, to have the pulp as it left the classifier contain about 2½ parts of water to one part of ore, as it was desired to send the pulp directly to the oil-flotation machines without the intermediate operation of dewatering it. Naturally the work of the classifier was very materially affected by this thick pulp, but in reducing the capacity of the classifier to separate the finished product from the oversize, it brought out very clearly the effect of the classifier on tube-mill efficiency; for, if the classifier had been of ample capacity to do efficient work, the results observed on account of its lack of capacity would not have been noticed.

Effect of Classifier on Capacity

It was observed that when feeding the tube-mill with material 6-mesh and finer, at the rate of 144 tons dry ore per 24 hours, about 8 per cent of the product remained on 100-mesh screen, with about 70 per cent of minus-200. Practically no material was returned from the classifier, so that in effect the tube-mill was producing a finished product as above. In order to maintain the desired density of the pulp flowing from the classifier, it was not practical to send the feed to the classifier, but directly to the tube-mill, using the classifier only to separate and return to the tube-mill the oversize from its product. When the feed was in-

creased substantially to more than 144 tons, oversize began to be returned by the classifier. About 210 tons per 24 hours was the limit of capacity of the classifier, when making a clean separation.

When the tube-mill was fed at the rate of 240 tons per 24 hours, a screen analysis of the classifier overflow showed 15 per cent remaining on 100-mesh screen, with about 56 per cent minus-200; and in the return to the tube-mill from the classifier there was 22 per cent plus-100 and 16 per cent minus-200. This showed that if the classifier had had capacity to separate the oversize from finished product, the 16 per cent of minus-200 which was returned with the oversize to the tube-mill would have passed out with the discharge from the classifier, making a total of 72 per cent minus-200; and if in making this separation 7 per cent of the material under 60-mesh and on 100-mesh had passed out from the classifier with the oversize where it belonged, there would have been left the 8 per cent on 100-mesh in the overflow as in the first case.

Under the first condition, with the classifier practically inoperative and returning no oversize, the tube-mill was making 92 per cent of 144 tons, or 132.48 tons, of minus 100-mesh. In the latter case the tube-mill in connection with the classifier returning oversize, was grinding 92 per cent of 240 tons, or 220.8 tons, of minus 100-mesh product; but the classifier did not do its work properly, as 30 per cent of the material returned to the tube-mill was minus 100-mesh and considerable oversize went off in the overflow from the classifier. Later when the classifier was changed it was found that there was no more plus 100-mesh product made when the tube-mill was grinding at the rate of 240 tons per 24 hours, with a classifier returning the oversize, than there was when it was grinding at the rate of 144 tons per 24 hours with no oversize returned from the classifier. These results would indicate that the efficiency of the tube-mill was decidedly greater when worked in closed circuit, than when it was attempted to deliver a finished product direct from the tube-mill in open circuit.

Results at a later period, when a still larger classifier had been installed, showed that the tube-mill worked even more efficiently when fed at the rate of 288 tons per 24 hours. In fact, every time during this period of three months when we thought we were beginning to reach the capacity of the tube-mill on a certain feed and to produce a certain mesh product, we would find that what we had really determined was the capacity of the classifier used in connection with the tube-mill and not the capacity of the tube-mill itself or of an efficient combination of tube-mill and classifier.

Effect of the Pulp-Load on Efficiency

A recording watt-meter was used in connection with the motor driving the tube-mill, and the observations taken from this record showed that the load of pulp which the tube-mill was carrying had a most decided effect upon the ultimate duty or efficiency of the tube-mill by its effect upon the power necessary to drive it. With a feed at the rate of 144 tons per day containing about 40 per cent moisture, the motor took 75 kilowatts. With a feed at the rate of 240 tons per day containing about 38 per cent moisture, the motor took 62 kilowatts. At another time with a feed of 180 tons per day with 38 per cent moisture, the motor took 70 kilowatts. By reducing the moisture in the tube-mill discharge to 30 per cent, by increasing the amount of material returned from the classifier, thus making a heavier floating load in the tube-mill, the power was reduced to 65 kilowatts. When the tube-mill was fed at the rate of 350 tons per 24 hours, feed containing about 40 per cent moisture, only 55 kilowatts was required to drive it. It would seem clear, therefore, that in making a comparison of the first two conditions, namely, (1) grinding 144 tons of dry ore all from 6-mesh feed to minus 100-mesh product, without any classifying; and (2) grinding 240 tons of dry ore all from 6-mesh feed to minus 100-mesh product with a classifier returning the oversize; it is evident that, not only was the capacity increased by using the classifier in closed circuit with the tube-mill, but the efficiency of the tube-mill was also increased by having a greater floating load, due not only to its ability to handle a larger amount of floating load, but also to a greater floating load from the amount of oversize in the closed circuit. The reduction in power necessary to drive it was from 75 kilowatts to 62 kilowatts.

To emphasize this point: If we assume that power costs 1 cent per kilowatt hour, then the cost for power per ton of ore ground in the first case would be twenty-four hours times 75 cents, amounting to $18.00 for 144 tons of ore, or 12½ cents per ton. In the second case, the cost for power per ton of ore ground would be 24 hours times 62 cents, amounting to $14.88 for 240 tons

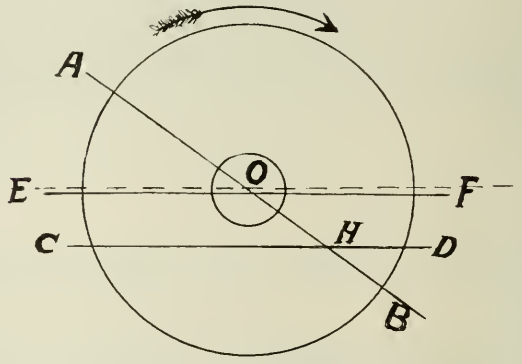

FIG. 1—CROSS-SECTION THROUGH TUBE-MILL

of ore, or 6 2/10 cents per ton. This certainly is one answer to the question as to whether the tube-mill is more efficient when operated with or without a classifier in closed circuit.

The results of my observations over this period of three months on this particular tube-mill, showed plainly that, with a given load, the power decreased very rapidly as the density of the pulp was increased, starting with a density of two parts of water to one part of ore and reducing the amount of water to 30 per cent. This was the greatest density obtained at any time, but there was no indication of congestion or clogging; and with a load at the rate of 240 tons per day, I would have liked to reduce the moisture still further if it had been practical. Of course the adjustable quick discharge attachment had the effect of lowering the discharge opening below the feed opening and increasing the flow of pulp through the tube-mill.

The pebble load is an unbalanced load. The pulp, or the floating load, is a balanced load. Any increase in the weight of the latter, due either to increasing its density or increasing the amount by carrying a greater quantity of material in the circuit, is bound to decrease the power necessary to drive the tube-mill. Referring to Fig. 1, let AB represent approximately the pebble load in action; let CD represent a certain pulp-load level; let EF represent another pulp-load level; let O represent the center of discharge opening. Then the more closely the triangle BHD approaches the triangle BOF in quantity or the triangle AOE in weight, or both, due to increased density, the less will be the power required to drive the mill. The instantaneous effect of changing this factor in the operation of the tube-mill, as shown by the recording watt-meter, was most interesting, and both the mill crew and visitors were much surprised at the results shown.

Chicago Heights, Ill.

The Use of Hydrometallurgical Apparatus in Chemical Engineering

BY JOHN V. N. DORR

(*Concluded from page 59 of the January issue*)

The Dorr Thickener

The Dorr thickener was developed by me in 1906, when, in remodeling a mill in the Black Hills, I desired to thicken the slime pulp from classification continuously in large units and avoid the use of the large cones which accumulated solid slime on the sides and gave much trouble.

The trial machine was operated in a tank 35 ft. in diameter by 12 ft. deep at a speed of 1/20 r.p.m. and gave excellent results, continuing in operation until the mill burned five years later.

DESCRIPTION

The Dorr continuous thickener consists of a slow-moving mechanism placed in a suitable tank, by means of which the operation of settling may be made continuous through the removal of the settled material to a point of discharge and the prevention of its accumulation as a solid in the tank.

As usually furnished, it consists of a central vertical shaft with radial arms equipped to bring the thickened material to a discharge opening at the center by the slow rotation of the mechanism. The thick material may be discharged by gravity at this point into a launder, or piped to the side of the tank and raised by air lift or pump to the level of the overflow or higher.

The machine is arranged for raising the shaft so that the arms will not be imbedded in the thick material if the power should be shut off for any length of time. The shaft can be lowered again gradually while running. Shaft and gear bracket are supported by a bridge over the tank or suspended from the roof trusses (Fig. 5).

In one case, at the Liberty Bell mill, thickeners have been installed driven from below the tank through a mercury bearing, and proved efficient, although they cannot be raised.

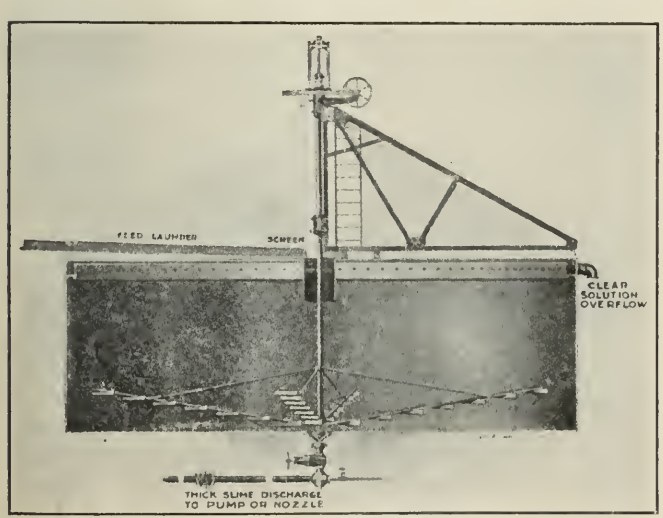

FIG. 5—DORR CONTINUOUS THICKENER

The thin pulp is delivered near the center of the tank in a suitable well with a float to cause minimum disturbance, and the overflow is taken off by a peripheral launder.

The thickened pulp can be accumulated and withdrawn at intervals, or a continuous discharge maintained, as desired. Nozzle discharge is in use in some concentrating mills where a comparatively thin pulp is desired, and also in one case where a product of only 30 per cent moisture is being obtained. Many are using diaphragm pumps for this purpose. They have the advantage of ready regulation and require little attention. Having a positive displacement, they tend to regulate automatically the amount of solids withdrawn, for, when the pulp becomes thicker, more solids are pumped with each stroke. A pet cock to admit air into the suction has proved most satisfactory as a means of regulation.

SPEED

The thickener has been operated at speeds ranging from 1 revolution in 2 minutes to 1 in 40 minutes. A quick-settling sandy material will offer great resistance unless a comparatively high speed is maintained, while colloidal slime will give a slightly thicker underflow, at a very slow speed. It will be found when handling sandy material that if the sand accumulates so that it is being moved around the tank by the channel arms as well as being advanced toward the center by the plows the resistance increases rapidly and the speed should be increased.

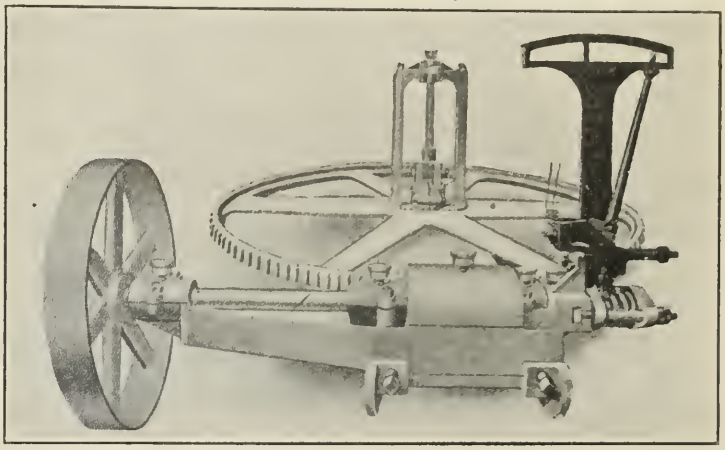

FIG. 6—OVERLOAD ALARM AND RESISTANCE INDICATOR ON DORR THICKENER, WITH ARRANGEMENT FOR RAISING SHAFT WHILE OPERATING

POWER

This varies with the size of the tank and the nature of the feed. Of course, the motor input is much larger than the actual power consumed, owing to the low load factor commonly used, as it is essential to have power enough to meet an unusual strain. Spring measurements have shown approximately 1/20th hp. being transmitted to the worm shaft of a 44-ft. thickener handling a classified slime. It would not be advisable, however, to install less than a 1-hp. motor on a single machine, but ½ hp. each can be allowed when several are driven from one lineshaft.

REPAIRS

Normal operation of the thickener causes no wear except on the worm, and many machines are running to-day that have not cost a cent for several years. On the other hand, if started after a shutdown without raising, a strain of any amount may be given so that the "weakest point" would have to yield.

The overload alarm, Fig. 6, is arranged to indicate the resistance offered by the mechanism as shown by the thrust on the worm shaft and to ring an alarm when the load becomes excessive. A solenoid or other means can be used to correct automatically the condition causing the excessive load, by reducing the feed or

increasing the underflow. The alarm has proved very valuable, especially on quick-settling pulp, when it is desired to obtain the thickest discharge.

LABOR

The attendance required varies with the regularity of conditions maintained and is usually confined to lubrication once a shift, so that the care of the thickeners is included in the duties of some man employed principally on other work.

CAPACITY

The capacity of Dorr thickeners on any pulp has been found to be primarily a function of area, although the depth of the tank has an influence depending on the dilution of the feed and the dilution of the underflow desired. With a given area and depth and a very dilute feed and underflow the capacity depends on the amount of liquid that can be clarified; i.e., additional solids, but no additional liquid, can be added to a tank already fed to capacity without overflowing slime. On the other hand, with a feed perhaps 8 of liquid to 1 of solids and a thick discharge of 2 to 1 or less, it will be found usually that additional liquid can be added to a thickener operating at capacity without overloading it, but any addition of solids will cause slime to overflow.

If a plant requires more settling capacity, raising the temperature of the solutions may prove an economical way to add 10 to 20 per cent. The capacity of any filter can also be increased by this means.

Table II represents data given me from time to time. It shows the settling area in use per ton in different mills which in many cases were not feeding their thickeners at capacity.

DENSITY OF UNDERFLOW

This depends on the nature of the pulp to be settled and the size of the particles. An argillaceous pulp, such as that at the Liberty Bell in Colorado, although containing a large percentage of reground siliceous material, will not settle thicker than 60 per cent moisture, while a finely ground quartz will give as low as 27 per cent moisture. At the Porcupine-Crown plant, handling a quartz product of 75 per cent minus 200 mesh, the average final pulp discharged contains 30 per cent moisture with the feed at the rate of 1 ton of solids per day for each 4.7 sq. ft. of tank area.

We have no reason to think that the use of the Dorr thickener will increase the amount of water that can be clarified in a given settling area at the beginning of the flow into the tank, but the removal of the pulp as rapidly as it settles certainly avoids the decrease in the settling rate which would follow when a tank is filling up in intermittent settling.

At one plant where reground ore pulp was thickened from 10 to 1 to approximately 2 to 1, actual experience indicated that the change from intermittent to continuous settling enabled three tanks equipped with Dorr thickeners to do the work of five used intermittently.

THE DORR TRAY THICKENER

The original thickener was installed in a tank 12 ft. deep and we adhered to approximately that depth, varying from 6 to 16 or 20 ft., for a number of years. One reason for this was that it early showed itself to be an advantage to have ample storage capacity for thickened slime at the bottom of the tank. It not infrequently happens that the flow of slime to the settling tank will vary during the day and the settling qualities of the slime may vary as well so that if the feed is light a large quantity of clear liquid accumulates on the top of the thickener, which when more slime comes, flows away, together with the freshly clarified water and partly thickened slime takes its place, thus giving a great reserve capacity.

Table II—Operating Data on Dorr Thickeners

Mill	Sq. Ft. Settling Area per Ton of Solids Thickened per 24 Hr.	Sq. Ft. Settling Area per Gallon Overflowed per Minute	Remarks
San Rafael, Mexico	4.5	.	Tube-mill product, 75 per cent. −200 mesh, discharge 45.5 per cent. solids.
Liberty Bell, Colorado.	15.0	12.6	Tube-mill product, much light argillaceous slime. Discharge 33 per cent. solids: + 100, 17 per cent.; + 200, 13 per cent.; − 200, 70 per cent. Feed 9:1. Solution fed at capacity; solids not. Large area per gallon overflowed per minute due to density of underflow and nature of the slime.
Mogul, South Dakota.	3.92	. . .	Tube-mill product; ore siliceous: + 60, 0.6 per cent.; + 100, 7.8 per cent.; + 200, 26 per cent.; − 200, 65.6 per cent. Discharge 56 to 59 per cent. solids. Continuous decantation.
Batopilas, Mexico	0.6 to 0.9	.....	40-mesh product; 90 per cent. passing 100 mesh.
Zambona, Mexico	3.1	.....	Tube-mill product. Discharge 40 per cent. solids.
Dominion, Ontario	5.4	.....	Tube-mill product, 88 per cent. − 200 mesh, ore diabase. Discharge 40 per cent. solids. Feed 6:1.
Porcupine-Crown, Ontario.	4.25	.....	Tube-mill product, 75 per cent. − 200 mesh. Discharge 65 per cent. solids. Quartz ore. Continuous decantation. With 5.1 sq. ft. settling area per ton settles to 71 to 73 per cent. solids.
El Palmarito, Mexico.	4.5	.....	Tube-mill product: pure quartzite, 97 per cent. − 200 mesh. Feed 7:1. Discharge 65 to 70 per cent. solids. Continuous decantation.
Amparo, Jalisco, Mex.	4.9	1.4	Tube-mill product, siliceous: 93.5 per cent. − 200 mesh. Feed 24.5:1. Discharge 23.5 per cent. solids: used to feed vanners.
Veta Colorado, Parral, Mex.	5.0	3⅓a	Tube-mill product, rather argillaceous: 71 per cent. − 200 mesh. Feed 11:1. Discharge 33 per cent. solids for agitator Have settled to 65 per cent. solids.
Smuggler-Union, Telluride, Colo.	.....	.....	Very clayey slime with classified sand. Screen test: + 40, 1.48 per cent.; + 60, 7.27 per cent.; + 100, 14.81 per cent.; + 200, 11.63 per cent.; − 200, 65.81 per cent.
	30.0	26.0	Settling from cold water, slightly alkaline. Feed 8:1. Discharge 50 per cent. solids, 1.429 sp. gr.
	10.0	.....	Settling from cyanide solution. Feed, 2.5:1. Discharge 40 per cent. solids, 1.316 sp. gr.
A large copper company, Arizona.	11.6	8.11	Considerable argillaceous slime. Feed 10.4 per cent. solids. Discharge 25.3 per cent. solids.
Pennsylvania Steel, Lebanon, Pa.	14.2	2.48	Thickening ahead of vanner concentration. Feed 2.8 per cent. solids. Discharge 10.6 per cent. solids. Overflow 0.4 per cent. solids, extremely fine, which does not interfere with using water again.
Nevada Consolidated, Ely, Nev.	... ..	1.25	"Each 17-ft. thickener supplies wash water for 20 Wilfley tables and occasionally for wash on vanners. One thickener has a greater capacity than twelve 8-ft. cones." Area of 17-ft. tank is 226 sq. ft.; of the twelve 8-ft. cones, 525 sq. ft.
Broken Hill, Proprietory, Australia.	.....	1.80	Dewatering slime from lead-zinc concentration mill. Feed 100:1. Dischrage 55 per cent. solids.
Anaconda Copper, Mont.	.....	5.95	Dewatering slime from concentrator. Forty 4-deck thickeners, each 28 ft. in diameter by 3 ft. 3 in. deep, handle about 26,000,000 gal. of pulp per day which contains approximately 2 per cent. solids. A clear overflow obtained, the underflow containing about 15 per cent. solids, which is fed to buddles.

The data given here show that when pulp is carried in cyanide solution a provision of 5 to 6 sq. ft. per ton for a siliceous tube mill product is ample and from 7 to 15 sq. ft. for a clayey material or classified slime product. When very dilute products are handled the area required is determined usually by the gallons per minute to be overflowed.
*Not up to capacity of overflow.

In 1913, however, I had occasion to go into the question of securing large settling capacity with small floor space and developed what I have called a tray thickener. There are two types of this. The first, which would seem to be the simplest, has been installed by the Anaconda Copper Company and in the Coeur d'Alenes. It consists of two or more shallow tanks, each carrying thickening apparatus attached to a common shaft and acting as independent units with its own feed, clear water overflow and thick slime discharge. Tests made by the Anaconda Copper Company indicated that with their material tanks 28 ft. x 3 ft. would handle approximately 90 per cent of the material, that tanks 28 ft. x 9 ft. would handle so that this gives them a great economy in plant construction.

Fig. 7 shows this type and represents one of forty

tray thickeners installed in their settling plant, which is handling 26,000,000 gal. of water a day and separating therefrom 2500 tons of extremely colloidal slimes. Each tray is a separate unit, with its own feed, thickened discharge and clear outflow.

The second type of tray thickener, which I have called the submerged type (Fig. 8) was tested first at the Homestake Mill at Lead, South Dakota, and consisted as tried there essentially of a shallow thickener and tank entirely submerged in a cone-bottom settling tank. The space below the small thickener had its own feed and discharge and the clear water overflowing from it joined the overflow of the shallow thickener tank. The latter has its own feed and discharge as well.

Fig. 9 gives the result of tests made there to show comparative capacities of tanks with and without the tray. Applying the idea to thickeners already installed, Fig. 9 shows the installation of a tray in a standard deep thickener. It gives in effect two tanks, each with its own feed and discharge, and a combined overflow, and in practice has resulted in enabling us to add 70 to 100 per cent to the capacity of plants already in opera-

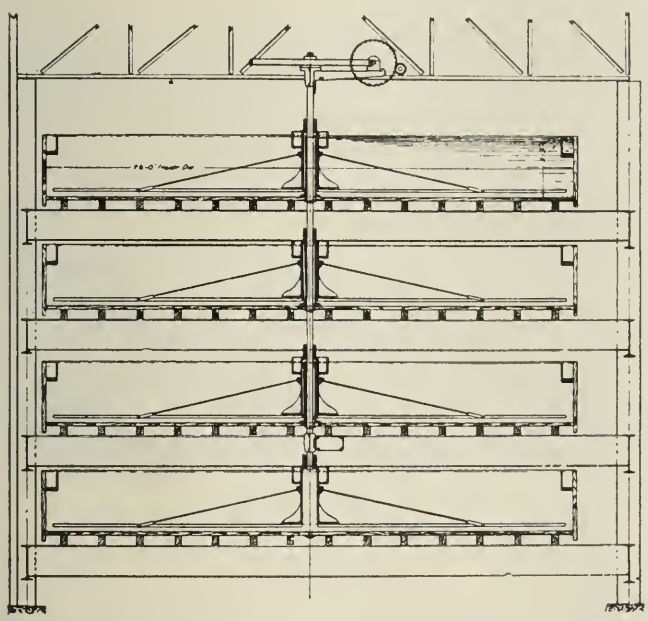

FIG. 7—THE DORR TRAY THICKENER, SUPERPOSED TYPE

tion. It has been found unnecessary to make this tray strong enough to support these tanks filled with liquid if the space below it is empty, as by means of an automatic float we have arranged to make connections between the upper tank and the lower in case the level of the liquid drops in either. It will be evident, I think, that these trays will afford means of obtaining a large amount of settling capacity with comparatively small floor space, and we are working now on their further development.

LARGE THICKENERS

For a long time the largest thickeners in use were in tanks 50 ft. in diameter by 20 ft. deep, at the Nevada Consolidated Company. Within the last year, however, the Arizona Copper Company has installed a Dorr thickener in a tank 130 ft. in diameter. Fig. 10 shows the machine in operation. It has proven entirely successful and indicates the possibility of furnishing very large unts which will cost less per square foot of settling area than the smaller ones. The tank in this case is merely a ring of concrete erected on a slag dump, the settled slime forming its own bottom. It is probably as large as any we would care to build, but we anticipate building up to 100 ft., using the bridge and central shaft, which we now use on our standard machine.

This large thickener has handled over 1200 tons of solids and Mr. David Cole, the company's engineer who designed and installed it, estimates that it would

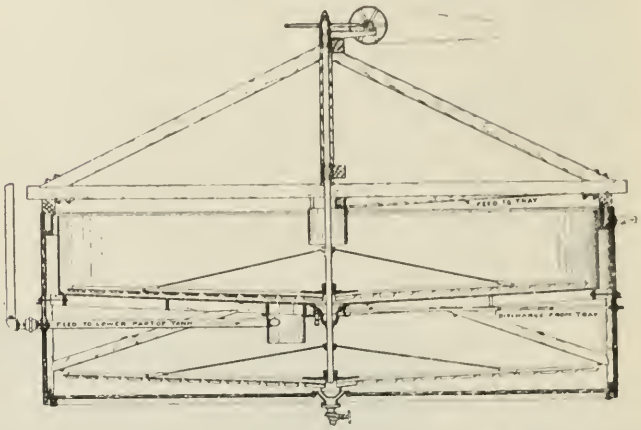

FIG. 8—THE DORR TRAY THICKENER, SUBMERGED TYPE

take care of 2000 tons of material 40 mesh and finer. Its overflow has been over 3,000,000 gal. per day, and its limit of capacity has not yet been reached. The net saving in water by the use of this machine with the mill at capacity is $120 per day.

It has proved feasible under some conditions to install a Dorr thickener in a rectangular settling tank and get good results.

USES

The thickener was originally introduced in cyaniding for thickening slime or reground pulp previous to agitation and filtration, and came into general use for that purpose. Within the last few years it has proved a

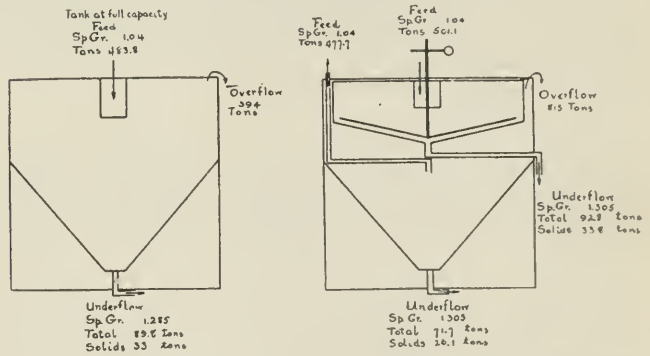

FIG. 9—TEST OF DORR TRAY THICKENER AT HOMESTAKE MILL, LEAD, S. D.

means for recovering the dissolved value as well by continuous counter-current decantation, which will be spoken of later. Its use in thickening ahead of slime concentration has become very general, nearly all the large copper and lead companies having adopted it within the last few years.

The development of flotation concentration has opened a new field for the thickener, the machine being used in most of the plants in this country and in Australia for dewatering both ahead of the flotation boxes and, in some cases, after them as well, also for collecting the concentrates and recovering warm water from the tails for reuse.

INDUSTRIAL USES

The thickener presents great opportunities for the recovery at an extremely small expense of all kinds of

finely divided residues that go to waste or are recovered intermittently from settling ponds. The expense, including interest on equipment, amounts in one case to 1 mill and in another 2 mills per 1000 gal. clarified. In both cases the solids removed were colloidal ore slimes. One plant recovering a finely divided organic material from settling ponds substituted the Dorr thickeners for them and I am advised saved the labor of 12 men per day. Its use for removing heavy silt in water purification seems possible with the large units now feasible.

Sewage treatment and its use for the prevention of stream pollution looks promising. A plant is now planned for the recovery of precipitated ferric-hydrate from mine water.

In all industrial work its use to furnish a much thicker product to a filter press will mean great increase in the capacity of the press with diminished costs.

CONTINUOUS COUNTER-CURRENT DECANTATION

Continuous counter-current decantation consists of the operation of a series of settling vessels in such a way that the solids to be treated continuously pass through them in succession, being diluted after each thickening by solution from the overflows passing in the opposite direction.

The objects to be attained are the dissolution under most favorable conditions of a portion of the solids, the separation of a solution from a finely divided solid with minimum dilution, or both combined.

The last result is that usually obtained in metallurgical work, as the separation of most of the dissolved material from the solids always occurs, and even when apparently adequate means for dissolution are provided ahead of the system the favorable conditions afforded usually give an additional extraction.

HISTORY

I will not take time to go into detail as to the history of continuous counter-current decantation, but simply say that the principles are very old and have been applied in many ways in chemical technology as well as in metallurgy.

The first cyanide plant using this method in the United States was erected by John Randall in the Black Hills in 1902, using large cones for settlers, and was operated for a year. The invention of the Dorr thickener in 1906 gave an opportunity to avoid the troubles inherent in cones, and in 1910 the first modern plant was started. Since that time there have been a large number of plants installed, several of them replacing vacuum filters, so that it may be regarded to-day as one of the well-established methods of cyaniding. Several years ago Dr. R. Gahl successfully operated an experimental plant with cone settlers, leaching copper ore slimes with sulphuric acid, treating seven or eight tons daily, to which he refers in a paper* read before the American Electrochemical Society. A test plant of 75 tons capacity is now starting, using thickeners.

The following description of a typical flow sheet of a continuous counter-current decantation cyanide plant will undoubtedly explain the process further, and also show the method we have used to determine the results that may be expected from any conditions assumed.

The square marked Mill, in Fig. 12, represents the grinding machinery, and we assume the ore is crushed in cyanide solution which brings the fine pulp continuously into thickener V, whence the solids pass through the agitators and thickeners W, X, Y and Z until discharged from Z as tailings.

Transactions American Electrochemical Society, vol. XXV, page 243 (1914).

All the figures on the flow sheet refer to tonnages of liquid per day.

The following conditions are assumed:

1st. The thick pulp underflows are thoroughly mixed with the clear overflows before entering the next tank, so that the dissolved gold is uniformly distributed through the liquid.

2nd. 100 tons of ore are milled per day.

3rd. $8.00 is dissolved per ton; 75 per cent in the mill, the balance in the agitators.

4th. The pulp from all thickeners is discharged at a ratio of 1:1 or 50 per cent moisture.

5th. 300 tons of solution is precipitated to a value of $0.02 per ton.

To determine the value of the solution from any thickener, if V, W, X, Y and Z equal the value in dollars per ton of the solution leaving each thickener, we get the following equations, as the same amount of gold and solution will enter and leave each tank:

(1) $400W + (\$6.00 \times 100) = 300V + 100V.$

That is, the gold in W, plus the additional gold assumed to be dissolved in the mill, equals the overflow and underflow of V.

(2) $100V + (\$2.00 \times 100) + 400X = 400W + 100W.$

The $(\$2.00 \times 100)$ represents additional gold dissolved in the agitators.

(3) $100W + 400Y = 400X + 100X.$

(4) $100X + 100Z + (300 \times \$0.02) = 400Y + 100Y.$

(5) $100Y + 100$ water (no value) $= 100Z + 100Z.$

In No. 4 the $0.02 represents the value of the precipitated solution returned to Y.

No. 5, representing a simple dilution with water, means that Z will have one-half the value of Y.

Solving these equations, we get the following values: $V = 2.656$, $W = 1.156$, $X = 0.286$, $Y = 0.076$, $Z = 0.038$, which may be checked as follows:

The gold precipitated.	$(\$2.656 - \$0.02) \times 300$	= $796.80
Lost in tailings	$(\$0.038 \times 100)$	= 3.80
Total		= $800.60
Total assumed dissolved	$(10 \times \$8.00)$	= 800.00
Discrepancy due to decimals		.60

From the above we deduce:

Assay value of solution precipitated	= $2.656
Dissolved loss per ton solution	.038
Dissolved loss per ton ore	.038
Percentage dissolved gold recovered	99.6

Similar calculations have shown that if one thickener is omitted from the flow sheet and no other conditions are changed the dissolved loss is increased to $0.133. Using the same four thickeners and precipitating 400 tons, instead of 300, the loss is cut to $0.08, while if the pulp can be discharged with 60 tons of solution, instead of 100, making it contain 37 per cent moisture, the amount precipitated can be reduced to 240 tons and the loss will only be $0.76 per ton of ore, although the solution precipitated will assay $3.321.

I should explain here that the reason the precipitated solution is added at Y, instead of Z, where it would obviously be more effective in increasing the extraction of gold, is that we have also a mechanical loss of cyanide to contend with. The 100 tons of water which can be added at Z to replace the liquid discharged with the tails reduces the strength of the solution lost to one-half when added to 100 tons of cyanide solution, whereas if added to 400 tons of solution it would reduce it only to four-fifths. A further saving in cyanide can be made by adding the barren solution at X, but this usually means adding an additional thickener on account of excessive gold losses.

It will be noted from these figures that the loss in gold can be regulated at will by increasing the solution

precipitated or the number of thickeners in the series, and also that pulp settling to 30-40 per cent moisture can be treated much more efficiently than pulp settling to 50-60 per cent. If pulp cannot be settled to 50 per cent or thicker it will usually be profitable to use a filter merely for dewatering at the end of the series.

DETAILS OF PLANT

The flow sheet shown, with what has already been said about Dorr thickeners, will give a clear idea of the construction of a continuous counter-current decantation plant.

The tanks in the series are either arranged on a level, in which case both the overflow and underflow must be elevated before being transferred into the next tank or in a series of steps so that the overflow goes by gravity from tank to tank, and only the smaller quantity of underflow is raised each time. Each method has its advantages.

The transfer of pulp is preferably done by a diaphragm or other pump of fixed displacement, as thereby a certain amount of automatic regulation is obtained.

Storage Tanks.—The more a flow sheet and the actual conditions of mill operations are studied the less additional storage capacity is felt necessary.

FIG. 10—DORR THICKENER INSTALLED IN A 130-FOOT DIAMETER TANK BY THE ARIZONA COPPER COMPANY

RESULTS

I realize that details of the technical results obtained in cyaniding will not be of great interest to chemical engineers, so will only say that when working on a hard, quick-settling ore ground to pass an 80-mesh assayer's screen or finer, which can be settled to a thick product containing 35 per cent to 50 per cent moisture, it has proved a most efficient means for the recovery of dissolved gold and silver from the pulp.

Compared with the usual filtration methods it has shown lower operating costs in spite of a higher mechanical loss in cyanide, and a higher recovery due to a lower loss of dissolved values and often to an additional extraction being made that could not be made commercially by direct agitation.

The following quotation from an article on "Continuous Counter-Current Decantation" in the *Engineering and Mining Journal* of October 31, 1914, sums up the conclusions reached at the Gold Road Mill, where continuous counter-current decantation was installed to replace a vacuum plant:

"The operators state that the principal disadvantage they found with the vacuum-filtration system upon their ores was that it was almost impossible to wash satisfactorily the cakes on the leaves. Cakes of uniform resistance could not be formed. They would crack badly and large sections would fall from them, making satisfactory washing impossible. Besides, the expense of labor, repairs and power is considerably more than is necessary in following the counter-current decantation system. They find practically no difference between the two systems in the amount of cyanide and lime consumed, perhaps a slightly greater quantity, amounting to about 0.1 lb. of cyanide, is being consumed in the decantation system.

"An advantage found with counter-current decantation is that the dissolution of gold is so perfect, due to the longer contact between the solutions and the pulp. The difference, considering all things, between leaf filtration and counter-current decantation, is at least 60 cents per ton of ore treated in favor of the latter."

This figure is higher than could be expected under usual conditions, but we have had definite statements of savings from the other plants that have changed as well. Information I have received from a number of plants operating indicate that on quick-settling ore from which $5.00 to $20.00 is recovered the mechanical loss in gold varies between 4 and 10 cents per ton of ore.

GENERAL CONSIDERATIONS—DISSOLUTION AND RECOVERY

From the nature of the process it is apparent that its use for dissolution is antagonistic to its use for recovery of the dissolved material, and although some have proposed the alternation of agitators and thickeners, I have always advocated where a high per cent of recovery in a concentrated form was required, as in cyaniding, all dissolution possible should be made ahead of the system. In other cases, as that described by Dr. Gahl, where it was essential to make the dissolution in stages so as to end with a nearly neutralized liquid and have the copper pulp when nearly finished meet fresh acid, it is, of course, essential, but calls for one series on dissolution and another on washing.

SCALE OF OPERATIONS

It will be seen that any continuous method of treatment of materials has greater relative advantages with an increase in size of operations and a continuous counter-current decantation plant with 50-ft. tanks will require no more labor, and, in fact, less than one with 10-ft. tanks, although it will have 25 times the capacity. As the actual labor cost for operating a series of thickeners is less than one man a shift, it will be seen that

if any washing or leaching operation is requiring the full time of one or more men this method can be considered if other conditions are favorable.

OTHER APPLICATIONS

Fig. 12 is intended to show a copper problem which I think will correspond to many problems that may occur in chemical industries, namely, the complete washing of finely suspended solids and the obtaining of the dissolved material in as concentrated a form as possible from which it is to be recovered by evaporation or complete precipitation, or by any other method, so that none of the liquid has to be returned to the system, as in cyaniding.

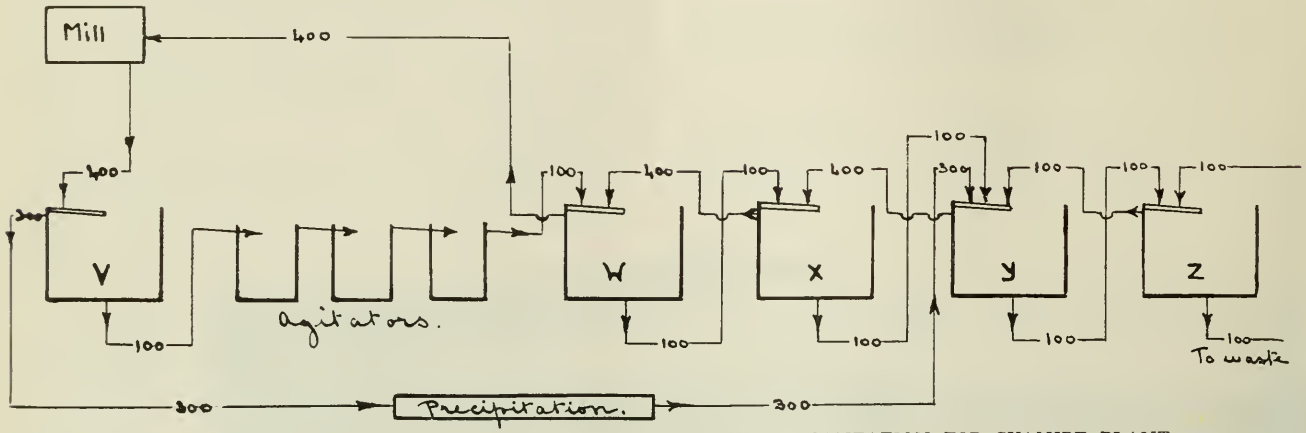

FIG. 11—EXAMPLE OF CONTINUOUS COUNTER-CURRENT DECANTATION FOR CYANIDE PLANT

CONDITIONS ASSUMED

(*a*) 100 tons of oxidized copper ore slimes treated per day.

(*b*) Slimes contain 2 per cent of soluble copper or 40 lbs. of copper per ton.

(*c*) Pulp is discharged from all thickeners with 41.2 per cent moisture.

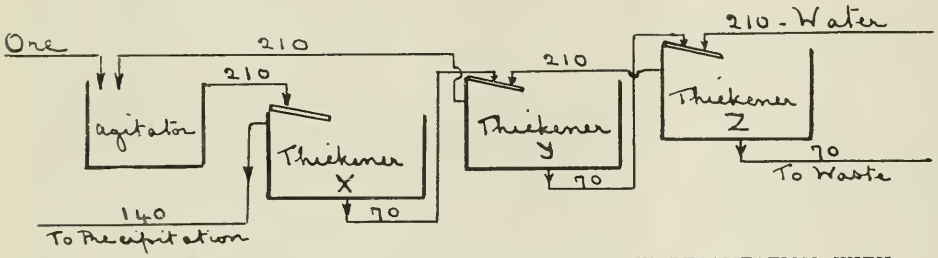

FIG. 12—EXAMPLE OF CONTINUOUS COUNTER-CURRENT DECANTATION WITH WASHING LIQUID NOT REUSED

Figures in Fig. 12 refer to solution tonnages.

(*d*) Inflow to each thickener is thoroughly mixed before entering same.

(*e*) 210 tons of wash water added to thickener "Z." The total overflow from thickener "X," 140 tons, sent to precipitation, and 70 tons sent to waste with the discharged residues from thickener "Z."

(*f*) Let X, Y and Z represent the pounds of copper per ton of solution discharged from the respective thickeners.

If we equate the inflow and outflow of each thickener in terms of tonnage and copper contents we have:

(1) $70X + 140X = 210Y + (100 \times 40)$ pounds
(2) $70Y + 210Y = 70X + 210Z$
(3) $70Z + 210Z = 70Y + 210$ tons of water.

Simplifying and solving we obtain:

X = 27.5132 lbs. copper per ton of solution.
Y = 8.4656 lbs. copper per ton of solution.
Z = 2.7164 lbs. copper per ton of solution.

From the above the following results are deduced:

1. Overflow to be precipitated, *i.e.*, X, contains 1.37 per cent copper, or 27.5 lbs. per ton of solution.
2. Solution wasted with the residues, *i.e.*, Z, contains 0.13 per cent copper, or 2.7 lbs. per ton of solution.
3. Copper sent to precipitation = 96.3 per cent of that dissolved.
4. Pounds of copper lost per ton of slimes = 1.48 lbs.

Varying the number of thickeners used and solution tonnage sent to precipitation, and assuming conditions *a*, *b*, *c* and *d* remain constant, we obtain the following results given in Table III.

It is apparent from this that the enriched solutions, which contain 96.3 per cent of the soluble copper, will carry 1.37 per cent copper per ton, and that you get no weak liquors at all for further handling. The additional tabulations show the results of changing various factors. You will see from this that precipitating 140 tons of solution, but adding a fourth thickener, increases the percentage recovered from 96.3 per cent to 98.8 per cent, with an enrichment of the solution from 1.37 per cent to 1.41 per cent. Precipitating 210 tons of solution, on the other hand, shows a solution to be precipitated carrying 0.93 per cent copper with three thickeners and 0.94 per cent with four thickeners, while the percentage of recovery is 98.5 per cent and 99.6 per cent. In other words, it is easy to see that by using the proper number of thickeners you can make practically any recovery desired and get any concentration you wish.

This method could be applied as readily to the manufacture of caustic from soda ash and lime, and I can say that a plant to use it to some extent has been purchased abroad, but its installation has been delayed by

TABLE III

Number of thickeners used	3		4		3		4	
Tons of solution sent to precipitation	140		140		210		210	
	Lbs. per ton.	Per cent.	Lbs. per ton.	Per cent.	Lbs. per ton.	Per cent.	Lbs. per ton.	Per cent.
Copper in the solution for precipitation	27.5	1.37	28.2	1.41	18.7	0.93	18.0	0.94
Copper in the solution wasted with the residues	2.7	0.13	0.7	0.03	0.9	0.04	0.2	0.01
Lbs. of dissolved copper lost per ton of slimes	1.48		0.49		0.63		0.16	
Per cent. of dissolved copper sent to precipitation	96.3		98.8		98.5		99.6	

the war. As the reaction between the soda and the lime requires a definite time it is possible that it might be necessary to do it in charges, but the same was believed true in cyaniding until it was demonstrated that continuous agitation with a series of agitators was better.

THE DORR AGITATOR

This machine, Fig. 13, was designed by me in 1910, but did not come into actual use until 1912, when about a half dozen machines were put out for trial purposes on a working scale at several different plants. The results obtained were so good that last year many more were installed in this country and abroad. During 1914, although mining in general has been very quiet, the use of them has increased greatly and from all installations made we have had nothing but satisfactory reports.

The illustration will give a good idea of the machine, which is very much like the Dorr thickener, the central shaft being replaced by a pipe, at the top of which distributing launders are arranged to distribute the pulp, which is raised through the pipe by means of air.

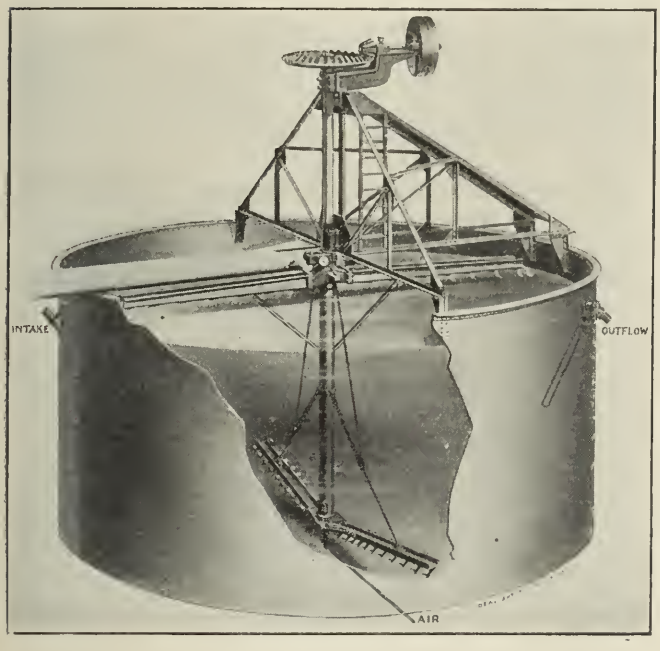

FIG. 13—DORR AGITATOR

A worm and sheaves provide means for raising or lowering the hinged arms at will.

In cyanide metallurgy mechanical sweeps in flat-bottomed tanks were first used for agitating the pulp, but the great difficulty experienced in most cases with these, including breakages and the power required, made the use of a high cone tank with a central air lift seem most attractive, and when it was introduced into this country and Mexico from Australia a very large percentage of the mills installed it.

At this time agitation was done in charges, but when continuous agitation became the established practice a few years ago it was found that there was a great tendency for the coarser material in the pulp being agitated to build up on the sides of the 60° cones used so that eventually the major portion of the agitating area became filled up with solids and the agitation only took place in a small cylinder in the center. It was also found necessary to give a much more violent agitation than the chemical treatment of the ore required in order to keep the pulp in suspension as much as possible.

The Dorr agitator, by the use of mechanical arms with the thickener plows on, which prevents settling of solids and brings the material from the bottom to the central uplift pipe, allows the regulation of the intensity of the agitation given to suit the chemical need of the ore and not the necessity for keeping everything in suspension.

EFFICIENCY

The value of an agitator depends on the cost of making the maximum economic extraction by its use. This will be determined by its cost of agitation per ton per hour and the time required to obtain dissolution.

All the data I have been able to obtain indicate that the cost of agitation per hour is extremely low. Extraction tests that have been made indicate that the rate of dissolution on both gold and silver ores in Dorr agitators, with a uniform although less violent agitation, is at least as rapid as in any other agitators with which it has been compared.

The most favorable conditions for the dissolution of gold and silver in cyanide solution vary with each ore treated. The maintenance of an excess of dissolved oxygen throughout the whole mass of pulp and the free movement of all particles of solids in the liquid immediately adjacent seem to be the only conditions that can be generally specified.

Definite work both in milling and the laboratory indicate that many ores will give a more rapid extraction and allow the use of a weaker solution when agitated as a dilute pulp of 3 to 1 or 4 to 1, and also cause less chemical consumption of cyanide.

The Dorr agitator, with its combination of air and mechanical agitation, gives a flexibility that is apparent, and it insures keeping all the solids in suspension all the time, whether the pulp is subjected to a gentle or a violent movement. This is essential especially in continuous agitation.

SELECTIVE AGITATION

The question of selective agitation was discussed by Mark R. Lamb.* As used here the expression is taken to mean continuous agitation under conditions which cause the coarser particles of the ore to remain in the agitator longer than the average time of treatment and thus give them the longer exposure they may require to obtain the best extraction.

This can be accomplished readily with the Dorr agitator by agitating at a dilution which allows the coarser material to classify out and discharging the raised pulp near the center while the outflow is taken from near the periphery. It will be seen that if a segregation takes place and the agitator is fed a pulp carrying 10 per cent plus 100 mesh, the discharge may be only 5 per cent plus 100 mesh at first. With twice as much inflow as outflow of 100-mesh material it will concentrate in the agitator while gradually increasing in the outflow until an equilibrium may be reached in which the feed and discharge will both be 10 per cent, and the average pulp in the tank 20 per cent, so that the exposure of coarse sand would be approximately double the average. While this is theoretical, enough work has been done to indicate that the idea can be put to practical use.

Dorr agitators have been installed in tanks of various sizes, the largest being those in use at the Desert Mill at Tonopah, Nevada, in tanks 36 ft. in diameter by 20 ft. deep. The company estimates that the total power required to operate one of these large machines, including mechanical horse power and the air required for maintaining agitation, is not over 5 hp., so you will see that it is extremely small. A recent measurement in a 20-ft. by 12-ft. agitator showed that 10 cu. ft.

*Transactions, American Institute Mining Engineers, vol. XL, p. 775 (1909).

of free air at 15 lb. pressure was all that was needed.

The application of Dorr agitators in the chemical industry has not been investigated to any extent, but it would seem that with finely divided materials from which it is desired to dissolve one constituent that they should perform as useful a function as they are now doing in metallurgy.

ACID-PROOF MACHINERY

As all the submerged portions of classifiers, thickeners and agitators have no reciprocal motion, it has not been found difficult to manufacture them so as to resist ordinary acid liquors and acid-proof machines of all three kinds are now in use.

Metal Production Statistics for 1914

The United States Geological Survey has issued preliminary reports on metal production during the past year. The figures are based on exact records for eleven months with careful estimates for December, and are considered very close approximations to the exact figures. From these reports we abstract the salient features.

Iron.—The quantity of iron ore mined in the United States in 1914 is estimated as between 41,000,000 and 42,500,000 long tons. In 1913 there was mined 61,980,437 long tons. The Lake Superior district is estimated to have shown a decrease in production of about 37 per cent, and a production of about 32,915,000 long tons. Prices generally were about 50 to 75 cents per ton lower than in 1913.

Gold.—This industry was prosperous in 1914, and the production is estimated to be about $4,000,000 greater than in 1913, totalling $92,823,500. Alaska output increased about $300,000, and Arizona showed an increase of about $500,000. In California the increase was nearly $700,000 more than in the previous year. The greatest increase was shown in Colorado, amounting to over $1,500,000, coming chiefly from Cripple Creek. Nevada, Idaho and Utah showed small decreases. The rank of the principal gold producing states was California, Colorado, Alaska, Nevada and South Dakota, as in 1913.

Silver.—All records for production of this metal would have been broken in 1914 but for the European war. As it was, the figures indicate an output of 67,929,700 ounces, valued at $37,225,000. Notable increases in production were made in Idaho, California and Arizona; decreases were noted in Montana, Utah, Nevada and Colorado. Nevada, however, still retains first place among silver producers, with Idaho, Montana, Utah and Colorado following in the order given. The general average price for the year was 54.8 cents per ounce, the lowest since 1911.

Copper.—The production of this metal will show a marked decrease compared with that of 1913, due to curtailment inaugurated in August and prevailing throughout the balance of the year. The output of blister and lake copper is estimated at 1,129,000,000 pounds in 1914 as compared with 1,224,484,000 pounds in 1913. Refined copper from foreign and domestic sources is estimated at 1,493,000,000 pounds as against 1,615,067,000 pounds in 1913. The average price for the year was about 13.5 cents per pound, being about 2 cents below the 1913 average. Arizona continued in first place among copper producing states.

Lead.—The production of this metal showed an increase of nearly 100,000 tons over the production of any previous year, and at the same time the average price for the year was the lowest since 1898. The estimated output was 537,079 short tons, worth at the average New York price $41,892,162, compared with 462,460 tons in 1913, worth $40,696,480. For the first time in years there were exports of domestic lead to Europe, the total for the year being estimated at 62,924 short tons, valued at about $4,804,000. The average New York price for the year 1914 was 3.9 cents a pound, compared with 4.4 cents in 1913 and 4.5 cents in 1912.

Tungsten.—The production of tungsten ores is estimated as equivalent to about 990 short tons containing 60 per cent WO_3. This is the smallest output since 1908; in 1913 the production was equivalent to 1537 tons. The production from Boulder county, Colorado, in 1914 was only 466 tons as compared with 953 tons in 1913. Prices ranged from $6.50 to $9 per unit (20 lb.) of WO_3. Of the various tungsten minerals, scheelite was produced in largest quantity, mainly from the Atolia district in the Mohave desert, Calif. Utah, Arizona, Idaho and New Mexico produced small quantities of ore.

Arsenic was produced only as a by-product from lead and copper smelting, but the output was the largest in the history of this country, amounting to 4227 short tons of arsenous oxide, or white arsenic. The 1913 production was only 2513 tons. The chief uses of this product are in glass making, for insecticides, and for killing weeds along railroad tracks.

Portland Cement.—The 1914 output of this material was approximately 88,514,000 barrels, compared with 92,097,131 barrels in 1913. The average value per barrel was probably slightly lower than in 1913.

American Institute of Mining Engineers

The annual meeting of the American Institute of Mining Engineers will be held in the Engineering Societies Building, 29 West 39th Street, New York City, from Monday, February 15th, to and including Wednesday, February 17th.

On Monday, February 15th, at 10 a. m. a meeting will be held on safety and sanitation in mining. In the afternoon two sessions will be held at 2 p. m. in different rooms, one on iron and steel metallurgy, the other on non-metallic minerals (clay, potash, etc.)

On Tuesday, February 16th, at 10 a. m. the annual business meeting will be held, followed by a technical session on various mining, metallurgical, and geological subjects. At 2 p. m. a session on fuels will be held by the committees on petroleum and gas and on coal and coke.

On Wednesday, February 17th, at 10 a. m., a session of non-ferrous metallurgy will be held, and at 2 p. m. a session on electricity in mines and mining.

The annual dinner will be held at the Hotel Astor on Tuesday evening, February 16th.

Inspiration Consolidated Copper Co. is completing its new mill of 10,000 tons daily capacity. Some changes may increase this to twelve or even fifteen thousand tons. Operations are scheduled to begin in April. The estimated cost of copper production is 8½ cents per pound.

The establishment of tin smelting in the United States is one of the possible industrial advantages that can accrue to this country as a result of the European war. Both Bolivian and United States interests might profit by such an arrangement, for Bolivia apparently has supplies of the raw material, and the United States is a large importer and consumer of the metal. Bolivia has been shipping annually from 30,000 to 40,000 tons of tin concentrates to Europe for smelting, while this country imports several times the quantity of tin represented in Bolivia's exports. The metallurgical problem would not be difficult, and the industry could be established here if transportation arrangements can be concluded.

Feldspar as a Possible Source of American Potash*

BY ALLERTON S. CUSHMAN AND GEORGE W COGGESHALL

Two years ago the authors presented a paper before the eighth International Congress of Applied Chemistry, entitled "The Production of Available Potash from the Natural Silicates." This paper** not only presented a general discussion of the work that had been done by a great number of investigators in this field, but also described the results of practical mill runs made by the authors on the large scale of operation. This work had been carried to a successful conclusion as far as the purely chemical engineering side of the problem was concerned, but for reasons which seemed important at that time, no presentation or analysis of cost data was included in the first publication.

As a rule, no worker is in general so much hampered by complex commercial situations in his particular field as the chemical engineer, and this is particularly true with respect to potash problems which rest more or less insecurely upon a network of local, national, and international regulations, economics, and special arrangements. The prices of crude and finished potashes have not in the past rested on the firm basis of cost of production and transportation, modified by the just law of supply and demand, but have been subject to unstable arrangements between national governments and international syndicates. The governments of great nations make bad partners for industrial enterprises in these uncertain days, for they themselves seem to be unable to guarantee the validity of their own contractural agreements. Furthermore, the fixing of prices of a necessity of industry and agriculture by international or national syndicates, by which the interest of the ultimate consumer can not be a prime consideration, is utterly opposed to the present-day tendency in the development of human affairs.

It is one thing to work out a complicated problem in chemical engineering to a successful technical working status on an encouraging basis of costs, but it is quite another thing to assume the responsibility of inducing capital to embark upon an unknown sea of enterprise, especially if this sea is strewn with uncharted rocks and shoals, one, at least, of which may represent the cutting of prices by foreign producers to or below the cost of production for a sufficient period to kill off newborn competition, with the idea of averaging up profits at some future time when the infant industry shall have been effectually strangled. As chemical engineers, however, we may take some comfort for the future from the thought that such premeditated arrangements are becoming unfashionable, if not dangerous.

It is the purpose of this second paper, which may be considered an elaboration of our earlier publication, to present the results of some additional investigation, together with a frank discussion of the cost data involved in the possibility of using American feldspars as a practical source of American potashes. Many workers in this field believe it to be a self-evident fact that the potash alone would not pay the cost of extraction, or, in other words, unless the potash yield was merely a by-product recovery in the manufacture of some valuable main product, the attempt to extract it would be foredoomed to failure. After having made a close study of certain phases of this problem, continuing over a period of many years, we wish to state that in our opinion the economic feasibility of turning to the feldspars as a source of potash is, to say the least, open to debate.

*A paper read before the American Institute of Chemical Engineers, at the Philadelphia meeting on December 2, 1914.

**Abstracted at some length in this journal, November, 1912, p. 727.

Feldspar can be obtained in unlimited quantity favorably situated to our freight and trade routes in this country, which will run quarry-wise 10 per cent in potash (K_2O). The raw material supply, as far as potash ore is concerned, resolves itself, therefore, into a mere question of economical quarrying operations at the usual well-known costs. A comparatively small quarry of such feldspar, containing 1,000,000 cu. ft. of rock, or 100 ft. in cube, would contain 17,000,000 lb. of potash (K_2O) which, if it could be extracted, would be worth even at ante-bellum prices, $700,000. One ton of such an ore would contain 200 lb. of potash, worth, if it could all be extracted, about $7. If we assume, however, that only 75 per cent of it would yield to a chemical engineering process, we still have $5 per ton in value to work for. When we remember that in large-scale operations in the gold-mining industries, quartz that carries no more than $2 per ton in valuable constituents has been profitably worked, the problem need not necessarily frighten us away at the outset.

During the fiscal year ending June 30, 1914, there was imported into the United States $15,000,000 worth of potash salts, kainit, manure salts, muriate of potash, and sulphate of potash. In addition to this, considerable quantities of caustic and carbonate of potash, not included in the later available statistics, were also imported. Of the total, $8,000,000 worth was muriate of potash. The fertilizer industry uses, of course, the larger proportion of these potash importations, the percentage in the last few years being about 85 per cent of the total of muriate of potash imported, there being left about $1,000,000 worth of muriate of potash which was used in industrial work. About half of this total, or $500,000 worth, was used to make caustic potash and carbonate of potash. These are used principally in the soap industries, although a portion is used as a wrapper-tobacco fertilizer and in the manufacture of glass, paper, preparation of colors, in printing, in photography, and in more strictly chemical industries. Some nitrate of potash is manufactured from the chloride. About one-eighth of the muriate is manufactured into chlorate of potash at present, which is largely used in the growing safety-match industry. Potash bichromate uses about one-twentieth of the muriate and this is used in textile and color industries; also in photography.

Before proceeding with an analysis of cost data involved in the possible use of feldspar as a potash ore, it will be well to consider briefly the present sources of the world's supply. The German mines, located principally in the neighborhood of Stassfurt and Magdeburg in Prussian Saxony, have been for the past seventy years the principal source of the world production of the various potassium salts. Prof. O. N. Witt, in an article in the *Chemiker Zeitung* of Oct. 8, 1914, states that borings in Alsace have shown favorable deposits which may prove to be of considerable value. This is interesting news in view of the present doubt as to the future political status of Alsace-Lorraine. The reported discovery of soluble potassium salts in the province of Catalana, Spain, has recently commanded considerable attention and was prominently mentioned in the last annual report of one of our large agricultural chemical companies. According to our latest consular reports under date of Nov. 6, 1914, potash has not been extracted in Spain up to the present time in commercial quantities.* If the Spanish prospects should develop so that they would become a basis of a world trade, they would be welcomed for breaking an existing monopoly, but the source of supply would still be oversea, whereas North American independence in the commodity is highly desirable.

*Consul General Carl Hurst's report in Daily Consular and Trade Reports, Dept. of Commerce, 261, 615.

An American source of potassium salts in any considerable or practical quantity, in spite of much expensive government and private exploration, has not yet been discovered. In the Far West the giant kelps of the Pacific Coast, some of the brines and bitterns of the saline lakes and wells, and the alunite deposits of Utah and Arizona have been proposed and studied as possible sources of potassium compounds. The fact remains, however, that up to the present time three-quarters of all the potassium salts used in agriculture are consumed east of the Allegheny Mountains, by far the greatest quantity going into the three states of North and South Carolina and Georgia.

The reasons for this segregated demand for potash fertilizers are not at once apparent. The authors have made inquiries and have received the following explanations: Cotton, tobacco, intensive orcharding, and truck farming use the largest quantities of artificial fertilizer, while, in addition to this, the educational propaganda of a large Southern agricultural chemical company has demonstrated in its more immediate territory the economy of the proper additions of fertilizer to the land. The great effort which is now being made throughout the country to bring up the yield per acre of all our crops, will in all probability largely increase the use of all fertilizing materials not excepting potash.

It is unlikely that even the Panama Canal under the present tolls system would enable Western potashes to meet European competition on the Eastern seaboard. The fact that the great feldspar dykes of the Appalachian system are in general located in close proximity to the places where potassium salts are in greatest demand makes a special appeal to the chemical engineer. That the growing use for potassium compounds in intensive agriculture and industry will some day make use of the huge quantity locked up in the silicates, seems a safe prophecy. Whether that time has yet arrived is now open to debate.

In this paper, the authors will confine themselves to a discussion of their own methods and chemical engineering experience. There is no intention to ignore the fact that other workers have also proposed or to some extent developed methods for extracting potash from feldspar, either with or without the simultaneous production of valuable by-products. With any or all such methods the authors are not in conflict or debate, the present object being merely to open the subject to discussion along a well-known line. If any other source or method of economically producing American potash is discovered, the authors will follow its development with much interest.

Our previous paper described the working of the process by which the insoluble potash in the feldspar rock was simply converted into the soluble chloride salt, but no separation of this soluble salt from the residual rock was made. The product contained about 4½ per cent water-soluble potash (K_2O) in the form of 7.1 per cent of muriate of potash (KCl), also about 16 per cent of free lime, and the balance was the insoluble mineral material. It was solely a potash-lime fertilizer.

Several hundred tons were produced in regular mill working, and twenty-four hour-a-day runs were made, so that the feasibility of producing this material continuously and regularly was fully demonstrated.

This fertilizer was distributed free of all charges to some score or more of state experiment stations and large growers in many states for field trials as a straight potash-lime fertilizer to be compared with other potash fertilizers, such as wood ashes and various mixtures.

The field results were very favorable, as was to be expected from a material of this composition.

As will be shown later, the cost of production of such a potash fertilizer was low but the added expense of freight charges on a material containing so much inert matter was a serious drawback.

Muriate of potash is the chief potash salt imported into this country. It is sold on the basis of "80 per cent muriate" and usually contains from 70 to 80 per cent KCl, or from 44 to 50 per cent K_2O. This material, having its values in such a small bulk, will bear the cost of freight shipment easily. It is the cheapest potash salt for use as a raw material for chemical manufacturing, and is also well adapted for mixing into general commercial fertilizers. Any potash salt, however, running not less than 17 per cent K_2O (or 26 per cent KCl) is adapted for use in mixed fertilizers. A salt lower than 17 per cent K_2O could only be used where the final K_2O content in the complete fertilizer was to be less than 5 per cent.

Therefore, for the uses of the fertilizer industry, the economical production of any material containing 26 per cent, or higher, of KCl, would find large use, but for the replacement of all or a portion of the one million dollars' worth of concentrated muriate salts used yearly in the United States for chemical manufacturing, it is necessary to produce a salt containing at least about 70 per cent KCl.

Our experimental work was continued with the idea of separating and concentrating the soluble potash salts unlocked by this process, and giving a product so concentrated and pure that it may be used either in making fertilizers or be worked up into other potash compounds for more strictly chemical uses.

The salts are easily leached out from the mass as it comes from the furnaces, and by proper methods a solution of about 10 per cent KCl can be obtained, using the wash liquors for leaching new material. The evaporation of large amounts of water is a serious problem in chemical industry and in this particular case it could not be accomplished cheaply by any of the usual methods of evaporation.

The engineers working on this problem, however, have had considerable experience with methods of evaporation by the direct use of hot waste stack gases. A Porion evaporator, using such gases, is an extremely cheap method of evaporation with furnace gases, provided the material in solution is not harmed by the gases themselves. Even cheaper than this is the method of spraying the liquor through the waste hot gases. Experience with this operation has developed such successful results that it was adopted for this particular work. This use of the hot kiln gases, otherwise wasted, has an added advantage in the potash process from the fact that any volatilized KCl is caught at the stack washer.

The chief technical difficulty in the conversion to KCl was due to the high temperature produced by the powdered coal flame. When the charge, moving down the kiln, is brought up to about 1050 deg. C. the reaction is complete and there is then present in the charge free KCl. If the material is then further heated beyond 1150 deg. C., some of the KCl is volatilized and passes as vapor toward the stack. This final over-heating of the charge, and the volatilization of KCl, may be prevented by the use of a rotating combustion chamber attached to the lower end of the kiln, the charge passing outside of the extremely hot zone which is inside the combustion chamber. This arrangement prevents all over-heating and is so effective that coal itself is dried by this means, in a rotary dryer, with heat from burning powdered coal, the hot zone being confined to the combustion chamber rotating with the kiln. Small burners must be used in such cases, however, and in this potash work it is better to over-heat than under-

heat the charge to obtain the full yield of soluble product. In the mill work described in our previous paper, when no rotating combustion chamber was used, about 16 per cent of the KCl was volatilized during its passage through the hot zone of the kiln. This is now all caught in the stack-washer.

The complete process for the final production from feldspar of potassium chloride salts similar to the concentrated muriates imported from Europe will now be outlined.

A mixture of ground feldspar, containing about 10 per cent of K_2O, and burned limestone, is formed into rounded aggregates or "clumps" about ¼ inch in diameter, by the device already employed, using a solution of calcium chloride for this purpose. Calcium chloride is the by-product of the ammonia-soda alkali process and is the reactive agent in unlocking the potash from the silica. Mixtures of powdered rock and dry calcium chloride are almost impossible to make due to the attraction of the chloride for moisture. Moreover, simple mixing of two materials in the form of fine powders does not give an intimate enough contact of the reacting particles to produce good yields in furnacing operations in which neither of the particles is melted, so as to "wet" the other. In this particular case it was found that a proportion of burned lime mixed with the powdered feldspar will unite with $CaCl_2$ from a solution sprinkled on the powder, to form an oxychloride compound which cements the whole powder into aggregates, giving such a very intimate union of the particles that when heated the reaction yields are high. These aggregates or "clumps" pass directly into the rotary kiln heated either by oil or powdered coal flame. The clumps fall out of the kiln in the same form in which they entered it, but the potash has been converted from the insoluble form into the water-soluble muriate. These red-hot clumps fall into water in leaching vats, where the potassium chloride goes into solution. Several of these leaching vats are used so that the solution of the salt, the leaching, washing, etc., is continually performed. The strong solutions are pumped to the evaporators. The weaker wash liquors are used as leaching liquids for a new lot of processed clumps. The strong liquor containing roughly 10 per cent of KCl will be continuously sprayed down through the hot gases passing out of the kilns to the stacks. This operation is well known and has been studied particularly by our engineers.

The bulk of the water in these solutions is thus evaporated and only very concentrated solutions or sludges are allowed to pass out. These very strong hot liquors are finally dried out in a rotary dryer placed at the head of the lime-burning kiln, using its hot waste gases. The crusts formed are then ground for the market.

The concentrated solution before complete drying contains a small proportion of sodium chloride, corresponding in amount to the proportion of Na_2O in the original feldspar. On a spar running 10 per cent K_2O the Na_2O content has averaged from 1½ to 2 per cent. This would give from the liquors completely dried at once, without any fractional separation of the NaCl, a product having about the following composition: KCl, 70 to 80 per cent; NaCl, 14 to 16 per cent, and the balance a very small amount of lime salts and moisture.

To compare this initial product with imported German muriates, we give in Table I analyses, upon which such salts are usually bought in this country.

It is thus seen that without any attempt at fractional separation, muriate of potash may be made from our American feldspars, equal in character to the usual imported muriates, and that they are as well adapted to be used in commercial mixed fertilizers as those imported.

TABLE I

	70/75 Per Cent Muriate	80/85 Per Cent Muriate
KCl	72.5	83.5
K_2SO_4	1.7	....
$MgSO_4$	0.8	0.4
$MgCl_2$	0.6	0.3
NaCl	21.2	14.5
$CaSO_4$	0.2	....
Insol	0.5	0.2
Water	2.5	1.1
	100.0	100.0

If the hot concentrated liquors are not at once brought to dryness but are given a fractional crystallization treatment, which may be made a continuous operation, whereby most of the NaCl is removed, the KCl crystals then obtained will run pure enough to enable their direct use in the manufacture of chemicals of a high grade of purity. It may be noted that the purchasing analysis of German "90 95 per cent muriates" runs KCl 91.7 per cent and NaCl 7.7 per cent.

However interesting a workable process may be, it must, in order to be successful, produce the final product at a cost less than that of the same material obtained elsewhere. The costs of producing muriate of potash by this process will now be considered somewhat in detail, as we wish to present this subject for the careful consideration of engineers and manufacturing interests in this country.

The plant required is equipped in a general way similarly to a Portland cement mill. There must be rock hoists, trackage, crushers, rolls, rock dryers, grinding mills, a rotary line burner, the "clumpers" and rotary kilns, coal dryer and grinder, besides bins, elevators and conveyors, also leaching vats, tanks for strong liquors and for wash water, pumps, flue arrangements at stack for spraying the liquors, dryers and pulverizer, also air compressor and general power plant, stairs, ladders, handrails, and buildings to house the plant.

Plant costs and annual charges. In order to get the best idea of the various costs, we shall take a concrete example of a plant large enough to handle 300 tons of feldspar per day of 24 hours, this plant being a good-sized commercial undertaking. Such a plant will require three rotary kilns each 100 feet long and from 7 to 8 feet in diameter. We may conveniently divide the plant costs into two parts: (1) Those for equipment usually present in Portland cement mills, and (2) those for special equipment and rearrangements necessary to carry out these potash processes.

(1) The equipment usually found in a cement mill of this size, which would be used in the potash work, is given in Table II.

TABLE II

Quarry hoists, trackage, cars and tools	$4,000
Crushers, rolls, grinding mills	17,140
Rock dryers	4,600
Kilns (3), 7 ft. diam x 100 ft. (to 125 ft.) long	24,000
Air compressor and piping	2,000
Power plant	20,000
Buildings, stairways, handrails, etc	16,000
Miscellaneous equipment (14 per cent)	12,260
Total	$100,000

(2) The special equipment and rearrangements required are itemized in Table III (p. 102).

Now, if 5 per cent interest and 7 per cent depreciation are figured on the first item of $100,000, the yearly

Table III

Belt conveyors	$850
Screw conveyors	1,350
Elevators	4,300
Feeders	600
Chutes and gates	1,140
Bins for dry operations and $CaCl_2$	7,000
Lime kiln and burner	5,000
Oil or coal bins and incidentals	1,000
Clumpers (3)	5,000
Leaching, wash tanks and supports	18,400
Stack alterations and spraying apparatus	1,800
Liquor dryer and stack	2,800
Stack base	400
Disposal system (sludge)	1,000
Pumps and solution piping	3,500
Line shafting, pulleys and foundations	700
Miscellaneous foundations	250
Miscellaneous walkways, etc	600
Contingencies	7,810
	$63,500
Superintendence, etc.	6,500
Total	$70,000

fixed charge is $12,000. It may be possible to lease a cement mill with this equipment for this amount per year, and, if production was desired rather quickly, such a procedure would recommend itself. If the annual charge on this investment is then taken as $12,000, and there is added to it 5 per cent interest and 10 per cent depreciation on the cost of the special equipment, $10,500, we have as the annual charges to plant investment $22,500, or $64.30 per day.

Raw Material and Costs. We think there is a quite general misunderstanding as to the cost of the feldspar for this use. The only considerable use at present for feldspar is for the production of white china and porcelain ware, and for this purpose it must be free from iron-bearing minerals, such as biotite, garnet, hornblende, tourmaline, etc., in order that it will burn white. Therefore, all the feldspar that is put upon the market must be hand picked and iron free, and for such material the prices run from $3 to $5 a ton. For the purpose of producing potash salts from feldspar, it is not at all necessary that the raw feldspar be free from iron. In fact, this process should rightly be called a process for producing potash salts from "feldspathic rock" instead of from "feldspar." Feldspathic rock underlies a large portion of the Appalachian system. Feldspar, free from iron, is a special mineral, occurring in dykes of high purity.

For the purpose of this business, what are now called "feldspar properties" would not necessarily come into consideration at all. The procedure would be to buy by the acre certain lands well located for the purpose and get the feldspathic rock out by open quarrying operations, the costs of which are low and are quite well known. Limestone is quarried rough for about 20 cents per ton and cement rock is quarried in the Lehigh district for about the same cost. We have figured the cost at 50 cents per ton, and have allowed an equal amount for freight, making the cost of crude feldspar at the mill $1 per ton. This low freight charge is made as it would be good policy to have the mill near the feldspar property, and we regard this cost per ton as obtainable. However, we later on give the change in the final cost of the product with change in cost of the raw feldspar. Three hundred tons of feldspar per day at $1 would be $300 per day or $105,000 per year.

The potash is unlocked from its combination as double silicate by the reaction with calcium chloride under heat, the potash and any soda present uniting with the chlorine, forming alkali chlorides. One part of K_2O requires theoretically 1.18 parts of $CaCl_2$, and one part of Na_2O requires 1.79 parts of $CaCl_2$. A feldspar rock containing 10 per cent K_2O and 2 per cent Na_2O will require 15.4 parts of $CaCl_2$. A charge of 300 tons of such feldspar will therefore theoretically require 46.2 tons of actual $CaCl_2$ and in practice some excess of the reactive agent is used. The technical difficulties encountered in making and handling mixtures of feldspar and dry calcium chloride and the means by which these difficulties were overcome, were fully described in our earlier paper. By having a small proportion of free quicklime mixed in with the pulverized feldspar, and by an automatic device by which a strong solution of calcium chloride is continuously sprinkled on a moving layer of the powder, separate aggregates or "clumps" are formed, due to the combination of the free lime with the calcium chloride, with the formation of an oxychloride compound which cements the masses together into an extremely intimate union. The chlorine seems to be in a much more reactive condition in this temporarily formed oxychloride compound than the chlorine in straight calcium chloride, although the higher reaction yields obtained may be due merely to the far more intimate contact of the particles composing the clumps. These clumps are run directly into the rotary kilns.

This automatic method of preparing materials for furnacing operations costs only a few cents per ton and in this and in other furnacing processes it is greatly increasing the reaction yields. It is one of those simple aids to chemical manufacturing procedure which is tending to make continuous operations replace the methods of treating separate batches, and while often increasing the yields, it always decreases the costs.

We shall therefore figure the costs, using for every one hundred parts of feldspar twenty parts each of lime and calcium chloride, or for the plant we are considering, sixty tons of each per day. Provision has been made for a rotary limestone-burning kiln. Limestone can be quarried, brought to the mill and crushed to rather small size for under $1 per ton. At this figure the raw material cost per ton of lime will be $1.70. The cost for burning will be 63 cents per ton, the items of this cost being shown below in the figures for furnacing the feldspar mix. This gives $2.33 as the cost in the mill for a ton of unground lime and the daily charge will be $140 or $49,000 per year. It may be mentioned here that unusual care in burning the limestone is not required, although good burning is advisable.

Calcium chloride is the by-product of the ammonia-soda alkali process and is produced in great quantities in this country. A large portion of the amount produced finds no ready sale. It may be obtained in solid form containing about 75 per cent $CaCl_2$ and the balance water, or in solution in various strengths. The solutions used in our work are quite strong, between 35 and 40 per cent $CaCl_2$, so that the original solutions shipped in tank cars are suitable for the purpose. The questions of freight charges on the water content of solutions and solid cakes as affecting the final cost at the mill of the actual calcium chloride has been gone into quite fully, and we feel justified in stating that in our opinion the net cost per ton of calcium chloride at the mill should not exceed $7.33. The sixty tons required per day will then cost $440 and per year $154,000. However, we later on give the change in the final cost of our product with change in cost of the calcium chloride.

Manufacturing Operations and Costs. Feldspar crushes and grinds more easily than limestone or cement clinker; it breaks easier due to its cleavage planes. It has been found that a high speed mill which will grind 5 tons per hour of crushed limestone so that 65 per cent

will pass a 100-mesh screen, will grind 8 tons of crushed feldspar to the same degree of fineness. The operations of crushing, preliminary grinding and fine grinding of the feldspar and the lime so that over 95 per cent of the mixture will pass a 100-mesh screen will cost about 16 cents per ton for power, 14 cents per ton for labor, and 10 cents per ton miscellaneous expenses, making 40 cents per ton total. The labor charge is for three shifts of six men each. This gives the cost for crushing and grinding the feldspar as $120 per day or $42,000 per year. Using the same figure per ton, the crushing of the limestone and grinding of the burned lime is $24 per day or $8,400 per year.

The power required for the clumping operation is very small for a pump, elevator, feed roll and conveyor. Three shifts of four men each can handle it. The costs are per ton clumped, power 1 cent, labor 8½ cents, miscellaneous 3½ cents, total 13 cents, making a daily charge of $46.80 or $16,380 per year.

The furnacing charges for heating the feldspar clumps are considerably less than those for burning Portland cement, as less heat is required, the maximum temperatures in the kiln being about 1100 deg. C. or 2000 deg. Fahr. In our work with cement kilns it was found necessary to reduce the size of the coal burners, and cut the amount of coal fed in by at least one-third or overheating would result. The coal requirements in burning limestone in rotary kilns show about the same reduction from Portland cement requirements, although a ton of quicklime requires the heat from about 75 lbs. of good coal for the actual decomposition of the limestone from which it is made. We do not know the amount of heat evolved or absorbed in the union of K_2O with the silica and alumina in the formation of feldspar, nor do we know the amount of heat evolved or absorbed when CaO unites with the same substances. The following data, however, is available:

$(K_2 + Cl_2)$ — $(K_2 + O)$ evolves 114,120 gram. calories.
$(Ca + Cl_2)$ — $(Ca + O)$ evolves 38,990 gram. calories.

Using these figures above, in a double decomposition where on the one hand calcium is removed from $CaCl_2$ and unites as CaO with silicates and on the other hand potassium leaves its union as K_2O with silicates and unites with chlorine to form KCl, there is evolved an amount of heat equal to 1440 B.t.u. per pound of K_2O. This means that an amount of heat is evolved in the kiln at the reacting temperature, corresponding to 15.5 lbs. of coal for every ton of the charge heated in this process and by that much decreases the amount of fuel necessary to be burned. Our figures are 300 lbs. of coal per ton of burned clumps, but to this we add 20 per cent for the evaporation of the 17 or 18 per cent of water the original clumps contain. This gives a coal consumption of 360 lbs. per ton, or a cost of 45 cents per ton for fuel. Drying and grinding the coal costs 7 cents per ton of furnace product, power for the kilns 5 cents, a labor charge of three shifts of three burnermen each comes to 7½ cents per ton, and adding 5½ cents for miscellaneous expense gives 70 cents per ton furnacing charges on the 420 tons per day produced by this plant. The daily charge is $294 and for the year $102,900.

The leaching of the furnace product has been done in a small way, but it has not actually been carried out at present upon a large scale, as no plant has had the necessary equipment. A complete equipment has been designed for a mill of the capacity we are considering. Four leaching tanks per kiln, each with a capacity of 2800 cubic feet; one tank for strong liquor for each kiln, with a capacity of 5600 cubic feet; and one common wash water tank with a capacity of 19,600 cubic feet are provided, with all foundations, piping, pumps, walkways, etc. Also a re-arrangement of the usual stacks so that the liquors are sprayed down through the hot kiln gases and in the same direction in which these gases are traveling at the time, dampers, direct by-passes, and a system for disposing of the residual mineral sludges to the dump. The power cost per day figures to $10.80; the labor of three shifts of five men each to $39.00, and adding $10.00 for miscellaneous expenses, the charge to this operation per day would be $59.80 or $20,930 per year. A 10 per cent solution of KCl pumped to the stack evaporators, if concentrated to a 30 per cent solution, will require the evaporation of 10.54 tons of water per hour in the three stacks. If the coal runs 13,000 B.t.u., this means the total heat from 0.91 ton of coal per hour. There will be burned in the kilns 3.15 tons of coal per hour, and it will require only 29 per cent of the heat generated in the kilns to effect this evaporation. This strong hot solution, pumped direct to the final dryer between the lime kiln and its stack, will require the evaporation of 3.7 tons of water per hour, requiring the total heat from 0.317 tons of coal. There will be burned in the lime kiln 0.44 tons of coal an hour or an excess of 40 per cent. Should this not be sufficient to effect the complete drying of the crusts of muriate of potash, and if it was necessary to add 50 per cent to the amount of coal burned, the added cost would be $9.50 per day which would increase the total charges per day only 0.64 per cent.

The totals of the above costs are therefore

	Per Day	Per Year
Overhead expenses on plant.....	$64.30	$22,500
Raw Materials	880.00	308,000
Manufacturing operations	544.60	190,610
Total	$1488.90	$521,110

Product. In our operation of this process in a Portland cement plant, 83.2 per cent of the insoluble K_2O in the feldspar was converted into KCl. This was done in a short kiln only 55 feet long and better results are possible in longer and more efficient kilns. There is little doubt that 80 per cent can be obtained in the plant under discussion. From a rock containing 10 per cent K_2O there would be recovered, therefore, in the final product 24 tons of actual K_2O in the form of 38.03 tons of KCl. This product should be about 80 per cent strength, therefore the actual final product will be 47.54 tons per day or 16,639 tons per year, running 80 per cent KCl and a trifle over 50 per cent K_2O, a material identical with "80 per cent Muriate" imported from Europe.

The cost of this product figures to $31.32 per ton. Table IV gives the costs in cents per pound and in terms of fertilizer units.

TABLE IV

Product—	Per Day	Per Year
(80% KCl = 50.48% K_2O.. ..	47.54 tons	16639 tons
Actual KCl	38.03 "	13310 "
Actual K_2O	24.0 "	8410 "
Cost per ton of product.....		$31.32
Cost per pound of KCl—		
Overhead		0.0845 cents
Raw materials		1.1570 "
Manufacturing		0.7161 "
Total		1.9576 "
Cost per pound of K_2O—		
Overhead		0.1340 cents
Raw materials		1.8333 "
Manufacturing		1.1346 "
Total		3.1019 "
Cost per "Unit" of K_2O.....		62.04 cents

Each change of 50 cents per ton in the cost of the raw feldspar rock changes the final cost of the K_2O in the product 0.3125 cents. Each change in cost of $1.00 per ton in the cost of calcium chloride changes the final cost of the K_2O in the product 0.125 cents.

If 80 per cent muriate of potash has been heretofore used at a cost in this country of $37.50 per ton, there is thus shown a saving by the above process of over $6.00 per ton or 20 per cent profit on the manufacturing cost. All the materials for the operation are to be had in this country, and the costs as established by the first plant would not be increased in the future by any foreign complications. As to whether the German syndicate will continue after the close of the present war, we can only say that it seems probable, as under no conditions now foreseen will the Stassfurt potash deposits be separated from Prussia nor will Prussia be separated from her potash deposits.

A very large production of muriate of potash from American feldspar rock would probably invite price cutting after the war. A reasonably small production, such as outlined in this paper, might supply the requirements of certain industries and still not be a large enough proportion of the whole amount used in this country to warrant a price war. Wise governmental measures might enable even a very large domestic industry to be built up, which would make us independent of foreign materials for this valuable and essential ingredient of our fertilizers. If the crop yields per acre are to be increased in this country, some such independence may be necessary.

The permanent assurance that the fertilizers of this country may be supplied from domestic sources and that miscellaneous industries such as the soap, glass, match, color, photographic and strictly chemical industries using $1,000,000 worth of potash a year can be assured of a constant source of supply would go far to stabilize a great many of our manufacturers and would, by so much, be an item of true progress, as the raw materials are not at the present time used for any useful purpose whatever.

It may be of some interest to record in passing that the present war conditions abroad have caused the market price of muriate of potash to rise. Last week we were quoted this material at about $100 per ton. If a plant of the size we have been describing was put into operation by leasing a cement mill and expending $70,000 on additional equipment, which could be finished in three months' time, and if the muriate of potash was sold at one-half the present quoted prices, or $50 per ton, the profits figure out as $26,300 per month. After three months' operation the plant would have been paid for and at any time afterwards the plant could be scrapped and a good profit still be made on the enterprise.

We have made no attempt to put a value upon the large amount of by-product rock matter. In the plant we have considered, there would be produced, figured on the dry basis, about 370 tons of this residue per day. It would have a composition about as follows:

Silico (SiO_2)	65.8%	
Alumina (Al_2O_3)	17.4%	
Lime (CaO)	13.5%	
Magnesia (MgO)	1.0%	
Potash (K_2O)	1.9%	(?)
Soda (Na_2O)	0.4%	
	100.0%	

Owing to the volatilization of ferric chloride, the material is almost pure white and might find use in the glass, pottery, porcelain or brick industries. It is similar in chemical composition to some clays except that it has a higher content of lime and a considerable proportion of this lime is already combined with the silica. Some use in glazes might be found. Although high in alumina, certain glass products might be made, using it in mixtures, particularly plate glass and some bottle glasses. Its freedom from color is a point in its favor and also the assurance of practically constant composition and physical condition. If 50 cents a ton could be obtained for it after being dried, the income would be about $120 per day. This would reduce the net cost of the 80 per cent muriate product to $28.80 per ton, and the cost of the K_2O to 2.85 cents per pound.

Conclusion. In concluding this paper, the authors wish to record the fact that they are already familiar with many strong arguments which can be used against the advisability of attempting to manufacture potash in the United States.

It is frequently stated that the Stassfurt potashes could be sold in this country for about one-third of the prices which prevailed before the war and still yield profits to the foreign mines. Whether this statement is accurate or not, we have no means of ascertaining, but even if it is nearly true, it clearly proves that the words used in the introduction to this paper were not too emphatic, in which it is pointed out that special interest rather than the cost of production has controlled prices. If potash has any bearing whatever, through intensive agriculture, upon the production and price of food crops, however indirect this bearing may be assumed to be, the control of the product by any single interest is unquestionably hurtful to the best interests of the people of this country.

In the opinion of some more or less well-informed persons, potash is not nearly so important to growing crops as the other principal plant foods, combined nitrogen and phosphates. In other words, there is a tendency in certain quarters to believe that the propaganda in favor of the widespread necessity for potash ir fertilizers has been overdone and that our agriculturalists could rest contented with potash reserves in the soil for many years to come, provided other conditions are properly looked after. However this may be, it is difficult to persuade either the practical grower or the scientific agriculturist that he does not increase his yields and early bearing, by a wise use of potash in one form or another. Up to the present time, the statistics of our average crop yields per acre are not a source of pride to those of us who study such comparative data.

It is the earnest belief of the writers that the American demand for an American source of potash at a fair price will continue to increase in the future. Whether the time has arrived when any progress along this line can be made, still remains in doubt. The foregoing paper has been offered to the Institute with no pretence at settling this important question but merely as a contribution to which we invite the attention and consideration of chemical engineers and others who may be interested.

The Institute of Industrial Research,
Washington, D. C.

The Alaska Gold Mines company has started its new mill, the first unit of 1500 tons daily capacity having been placed in operation in January. It is expected that full capacity of 6000 tons daily will be reached by June. A special meeting of stockholders of the company was held Jan. 21 for the purpose of authorizing an issue of $1,500,000 ten-year, 6 per cent convertible debentures.

The Nipissing Mining Co. shipped from Cobalt during the month of December, 1914, bullion to the value of $535,864. The high-grade mill treated 175 tons of ore and shipped 1,093,510 ounces refined silver.

The Development of Continuous Counter-Current Decantation in Cyanidation of Slime

BY W. J. PENTLAND

Continuous counter-current decantation as applied to the cyanidation of slime from gold and silver ores, offers a simple, economical, and efficient method of treatment. The object of the process is to separate from the slime and recover the solution containing precious metals. The principle of the method, as its name implies, is to effect this separation and recovery by decantation of the valuable solution from settling slime, washing the dissolved metal from the slime by means of a counter-current of water and barren solution, and performing these operations continuously. The process is applied in a series of Dorr continuous thickeners, through which thickened slime flows from head to tail of the system, while washing solutions flow in the opposite direction. The slime becomes gradually impoverished and the solution steadily enriched. A general outline of the system is shown in Fig. 1.

Several years ago the opinion was held by some, and publicly expressed in the technical press, that the application of continuous decantation to the treatment of slime would be a backward step; that displacement by filtration was the logical mode of recovering dissolved metal from ore-pulp; and that dilution by decantation was illogical. Since that time, however, continuous decantation has continued to show economy in practice to such an extent as to render the former contentions untenable.

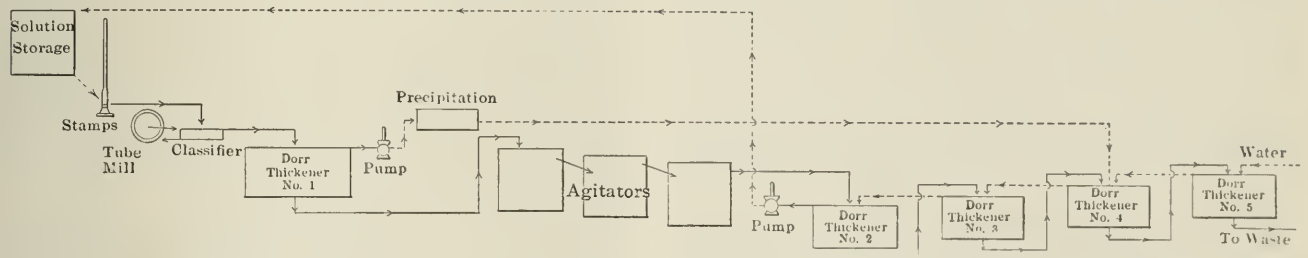

FIG. 1—DIAGRAMMATIC ELEVATION FLOW-SHEET OF CONTINUOUS COUNTER-CURRENT DECANTATION

Positive displacement methods, such as vacuum and pressure filtration, are theoretically ideal. They may even give better metallurgical results than can be obtained by dilution in continuous decantation; but if their economical results are inferior they must give place to more economical methods. As a matter of fact, continuous decantation has shown excellent results both in metallurgical extraction and economy of installation and operation, comparing very favorably with filtration processes.

The general adoption of a metallurgical system does not result from technical perfection alone; it is accomplished by superior economic results measured in dollars and cents. Filtration came into use, not merely because it was technically better than intermittent decantation, but because it was also economically better. It seems not unreasonable to assume that if, at the time operators were beginning to feel that some improvement on intermittent decantation must be developed, more attention had been given to continuous decantation, filters would not have come into such general use for recovering valuable solution, but would have been used mainly as dewaterers.

At the time filters were developed, however, satisfactory slime thickeners had not been produced, and attention was given to filters as offering the best solution of the slime-treatment problem. Subsequent experience with these devices showed that the anticipated displacement of 1 ton of solution with from 0.8 to 1 ton of wash was not obtained, and that in practice from 2 to 2½ tons of wash had to be given, thus producing considerable dilution. Operating cost, when complete washing was accomplished, was too high, and the desire for more economic results caused operators to look about for an improvement on filtration. In the meantime Dorr developed his continuous thickener which lent itself so well to schemes for handling slime continuously that continuous decantation received the impetus necessary to bring it into successful use. It is stated[1] that since 1910, when the first continuous decantation plant using these thickeners was operated, "over twenty plants have been erected or are now being installed to operate by this method."

Some Early Objections to Continuous Decantation

It was probably natural that when the process first came into use, more or less skepticism existed as to its feasibility, and that objections were raised that were due, in some cases, to a misunderstanding of the method. It is true that the process is not of universal application; but while it has its limitations, it is susceptible of a number of variations that make it widely useful.

Some opposition developed through a confusion of continuous decantation with continuous agitation. These are two distinct functions in ore-treatment; and if the ores to be treated vary so widely in character that different periods of agitation are required, the agitating equipment should be designed accordingly. Such provision has always been made for intermittent decantation, and the same allowance must be made in the case of continuous decantation. The troubles and deficiencies of agitation must not be shouldered onto continuous decantation; if the former does not meet the requirements of the ore, the latter cannot rectify the trouble.

Within ten days of the time of writing, I visited a mill where the change from intermittent to continuous decantation is nearing completion. The agitation system is intermittent as before, and designed to meet the requirements of the ore; but a storage or equalizer tank has been placed between agitators and continuous decantation system. This mill has been treating over 300 tons daily and the change has been made without interrupting the regular tonnage. The management expects the remodeled mill to treat a larger tonnage than formerly.

Another point on which some were skeptical was the possibility of classification occurring during the flow of pulp through the successive thickeners, whereby heavier or larger particles of ore would become segregated. We have found, however, that where the ore is homogeneous, and the crushing and grinding departments yield a uniformly fine product, noticeable differences do not appear in screen analyses of the pulp at different points in the system.

An exception to this condition may occur when the ore

[1] The Dorr Hydrometallurgical Apparatus. By John V. N. Dorr. *Bulletin* A. I. M. E., Aug., 1914, p. 2063.

contains two widely different gangue rocks, such as quartz and clay. A pulp of such material cannot be thickened beyond a certain point, and any attempt to do so will result in discharging the quartz from the thickeners faster than the clay, leaving the latter to accumulate until it appears in the overflow. The correct density for such a pulp must be determined by experiment in order to avoid this segregation. Should slime appear in the overflow of the thickener, the quantity of moisture in the discharge must be increased until normal conditions return.

Another objection, which probably is more valid than those mentioned, is raised in connection with ores of such physical characteristics that they do not settle readily, requiring a large unit settling area, and discharging from the thickeners with too high a percentage of moisture. In a plant of large capacity treating such an ore as this, the required plant for continuous decantation might be too extensive, necessitating buildings of large area. Under such conditions, filtration might prove preferable, perhaps following decantation in one or two stages. The decanting process would even then serve to reduce the value of slime sent to the filters, and hence minimize the loss of dissolved metal in the filter cake.

No Serious Trouble from Occasional Interruptions

When a sudden and unexpected interruption of power service occurs in slime plants, a charge tends to settle and pack in the bottom of the tanks. With Dorr thickeners, however, no serious difficulty is encountered in bringing the charge into circulation again. At the moment of stopping, the rabble arms can be raised above their usual position so that they do not become packed in settled slime. On starting again, the arms are gradually lowered to their normal position, disintegrating the settled mass and moving it to the point of discharge.

With intermittent decantation in ordinary vats the conditions are not so favorable. Sand and slime pack in the bottom and cause much trouble in resuming operation. At one intermittent decantation plant of cone-bottom tanks, I attempted to secure washing of the pulp by discharging it into these tanks previously filled with the wash solution. The desired washing was accomplished, but the excessive dilution allowed the sandy part of the pulp to settle rapidly and plug the discharge. This difficulty was finally overcome by leaving a part of the previous charge in the tank, which sufficed to prevent rapid settlement of the sand.

In continuous decantation with Dorr thickeners the cost for repairs, power, and labor is much lower than for intermittent decantation. Dorr states[2] that "many machines (thickeners) are running to-day that have not cost a cent for several years." Power cost is low, ½ hp being sufficient allowance to make for each thickener when several are driven from the same lineshaft. In fact, the power required for the entire plant below the tube-mills is surprisingly small. In the new mill for the Rochester Mines Company, at Rochester, Nev., a 15-hp motor is provided to run three agitators, six thickeners and the necessary solution and slime pumps and shafting.[3] As for labor, "at the Anaconda four men per shift are more than enough to care for 160 tanks thickening 26,000,000 gal. per day, containing 2500 tons of solids."[4] When these conditions are compared with the labor of attendants in an intermittent decantation plant, lowering and raising decanting pipes, starting and stopping pumps and agitators, recording the progress of many charges through the plant, sampling and calculating tonnage on each charge, etc., some idea of the advantages of the continuous system will become apparent.

As for comparative capacities, the continuous system will handle from 40 per cent to 60 per cent more ore than can be put through an intermittent system, and do it cheaper and better. Under continuous decantation every tank is in active service all the time, while with intermittent conditions the tanks are working actively only about half time.

Simplicity of Arrangement and Operation

For simplicity of arrangement and ease of operation it would be difficult to excel a properly designed continuous decantation plant. All of the thickeners and agitators can be placed on one floor below the level of tube-mill discharge. Slight differences in the level of thickeners permit gravity flow of wash solutions. When diaphragm pumps are used for the transfer of pulp from one thickener to another they are placed at the top of the thickeners, and as a result the flow of all slime and solution can be observed from one floor at the average level of the top of the thickeners.

Concentration of plant in a small area, when favored with facility of operation, makes easier conditions for the attendants who can then be expected to perform their work properly. Too often plants are built to satisfy only the technical plans in view, taking it for granted that the attendants can always find a way to do their work regardless of plant arrangement. So they can; but it takes more of them to do the work and they do it less efficiently than in a well-designed plant. When, with concentration of plant and facility of operation, we also have simplicity of arrangement we are indeed favored. These are all obtained in properly designed continuous decantation as developed at this time. Once the rate of flow of pulp and solution is established, attention to the plant becomes simple routine.

A number of valuable plant accessories have been developed to aid the operator in maintaining uniform conditions. Diaphragm pumps furnish a means of moving pulp with positive measurement; the mechanism gives little trouble or wear. Overload alarms on thickeners, with electric bell attachment and graphic indicator, provide a check against carelessness and possible accident from too dense pulps. In short a continuous decantation plant is as near fool-proof as could be desired.

Gravity Flow of Wash Solutions

The general arrangement of a continuous decantation system with relation to the other departments of a mill, appears in Fig. 1, showing the relative levels of the different units. The five thickeners and three agitators can be arranged on one floor of the mill. Diaphragm pumps, not shown, are used to raise the thickened pulp from thickener No. 1 to the series of agitators, and from thickener No. 2 to No. 3, 3 to 4, and 4 to 5. Solution pumps elevate the overflow from thickener No. 1 to precipitation and from No. 2 to storage. Otherwise the flow of solution is by gravity. The precipitating apparatus is placed high enough to allow barren solution to flow by gravity to the desired point in the system, and the last four thickeners have sufficient difference in level, say, 2 ft., to permit gravity flow in countercurrent to the slime.

At first sight one might think that as it is easier to maintain solution pumps than slime pumps in good order, it would be more logical to arrange a gravity flow of pulp than of solution. There are a number of serious objections to such a plan. In the first place, the

[2] Ibid.

[4] *Bulletin* A. I. M. E., August, 1914, p. 2060.

positive measured flow of pulp of uniform density is of great importance, and we cannot be assured of this by gravity flow through a fixed orifice. But if we transfer pulp by a mechanical device, such as a diaphragm pump, which at each stroke transfers a definite volume of pulp, we can easily maintain uniformity in the density of pulp transferred. If, temporarily, an undesirable change occurs in the density of the pulp, the pump will correct the condition; if the pulp is too thin, a larger relative volume of solution will be withdrawn at each stroke and *vice versa*. Such conditions cannot be obtained by means of a spigot discharge controlled by a valve. Furthermore, we have long since learned that the orifice of a valve plugs so easily as to condemn it for regulating the flow of pulp.

Another objection to gravity flow of slime through the system is found in the loss of mill-head that would result from the necessary arrangement of thickeners. With gravity flow of solution, the difference in level between thickeners is only about 2 ft., whereas an arrangement providing for gravity flow of pulp would require a difference in level between thickeners practically equal to the depth of the tank plus space for pipe and valve clearance. Thus the plant would resolve itself into a number of floors and the arrangement for driving the thickeners would be complicated. Furthermore, the power required probably would be greater, as approximately 1 hp would have to be provided for pumping solutions from tank to tank, as against 1/3 hp for elevating pulp by diaphragm pumps. In short, the arrangement of thickeners for gravity flow of solution gives us many advantages in construction, arrangement and power, and the elevation of pulp by diaphragm pumps corrects irregularities in density of the flow.

The air-lift can be used instead of the diaphragm pump for transferal, but it is usually not so satisfactory. It is especially recommended that the thickeners be equipped with overload alarms on the driving mechanism, and that the capacity of the lift be closely adjusted to the average flow of pulp.

The flow-sheet in Fig. 1 shows that the overflow from thickener No. 1 is precipitated. It is usually found unnecessary to precipitate this entire overflow in order to reduce the value of circulating solution. Any excess above the quantity precipitated can be returned to the mill-solution storage tank. In order to send a constant quantity of solution to precipitation, the overflow of No. 1 can pass to a receiving tank provided with a fixed orifice and overflow launder. As this tank will always be full, there will be a steady flow to the precipitation plant and thence to thickener No. 4. The excess solution overflowing the receiving tank can be combined with the overflow from thickener No. 2.

I recently visited a 100-ton mill using the continuous system, in which there were no sump or storage tanks. When operations were temporarily interrupted, the outlets of the overflow launder of the thickeners were plugged, thereby providing 8 in. or 9 in. additional depth in the thickeners for the storage of circulating solution until operations could be resumed.

Thorough Mixing of Pulp and Wash-Solution Necessary

A requirement of continuous counter-current decantation that must not be overlooked is the thorough mixing of wash-solution and pulp entering the thickeners. This can be accomplished by placing staggered baffles in the receiving launder and giving the latter sufficient fall from the periphery of the tank to the center to carry the mixed pulp through the tortuous path defined by the baffles.

From the launder the pulp can be received in a suspended central well in the form of a cylinder surrounding the vertical driving shaft of the thickener. The well can extend from 18 in. to 3 ft. below the level of solution in the tank and perhaps 1 ft. above. A suitable diameter for the cylinder would be also from 18 in. to 3 ft., depending on size of tank and dilution of pulp. Floating loosely within the cylinder, a wooden baffle can be placed to break the force of the incoming stream of slime solution. The baffle can be made in two pieces for convenience in case of removal, and it has an opening through which the vertical shaft passes. This device will reduce any tendency to form currents in the settling slime and will be an aid to quiet settlement, especially if the capacity of the thickener is being pressed to the maximum.

In case the thickeners are all on the same level, as for example in a remodeled plant, it may be necessary to make special provision for the mixing of pulp and wash-solution, as this cannot be done in launders.

To digress a moment, I see no particular advantage in the circular overflow launder that accompanies Dorr thickeners. This launder is expensive to construct and difficult to level, and it has but one side available to receive solution. Instead of this circular launder I suggest one of hexagonal form. For example, in a thickener of 24 ft. diameter, a hexagonal launder constructed of six 12-ft. sections could be supported in the tank at six points equidistant on the inner periphery. This launder would measure nearly 72 lin. ft. around its outer edge and nearly 66 lin. ft. on the inner, or a total of 138 lin. ft. available to receive overflow. A circular launder for the same thickener would measure about 75 lin. ft., and have but one side available.

Variations of Continuous Decantation

An important feature of the continuous decantation process as developed by Dorr is that, from data of tests on an ore, the probable results in practice are susceptible of close calculation in advance; and the counter-current flow of solution can be varied to give the most economic results as regards loss of dissolved metal and mechanical loss of cyanide in the tailing. Different ores present individual problems; but when the mechanical and chemical requirements of an ore are known, the calculation of results gives an accurate forecast of what may be expected in practice.

To obtain the most economical results, the counter-current flow of solution can be varied, but the flow of thickened pulp is always in a regular and unbroken line from head to tail of the system.

From what has been presented it would seem that we may anticipate a wider use of this method of cyaniding slime as its advantages become better known. In some cases it may be wise to meet special conditions by adding a filter to the system, to reduce dissolved metal loss or mechanical loss of cyanide, or to dewater tailings for stacking or conservation of water. No attempt should be made to impose on continuous decantation any duties that it cannot perform economically; but on the other hand, it should receive careful consideration wherever it seems applicable. Past progress in its adoption has been conservative, and each new installation has increased our knowledge of its possibilities.

Guadalajara, Jal., Mexico.

Aluminium alloys of different types have been patented by W. A. McAdams, of Bay Shore, N. Y. One is a soft alloy, suitable for making metal foil. It contains 100 parts aluminium, 30 cadmium and 5 tin. Another, designed to make cast objects that will not tarnish, contains 100 parts aluminium, 20 silver, 10 zinc and 5 copper. The third is a casting alloy containing 100 parts aluminium, 18 copper, 5 zinc and 3 antimony.

Limitations of the Electric Furnace in the Manufacture of Steel Castings

BY G. MUNTZ

In the September issue of *Metallurgical and Chemical Engineering* Mr. Ivar Rennerfelt takes exception to certain statements made by the writer in his article published in the June issue of the same magazine, under the heading of "Tropenas Converters vs. Electric Furnaces for the Manufacture of Steel Castings."

From the arguments advanced it is clear that Mr. Rennerfelt has misunderstood the purpose of the comparison made between the converter and electric processes in general. The writer's object in writing his first article was not to prove that metallurgically the converter was superior to the electric furnace, as doing so would be defending a paradox; we only tried to bring out the fact that the electric furnace represents the ideal means of producing ideal steel, but that the great problem is to determine whether or not its use is commercially possible. Cases such as this are not uncommon in any industry and the best example can be put in the shape of a question, namely, "Why is diamond not superseding tool steel?" The answer is one of commercial impossibility. Diamond represents an ideal, which, like others, cannot be used commercially.

Among various problems, none presents more difficulty of solution than that faced by the foundryman, who, at the crossroads of progress, must choose between the newer and yet uncertain melting method, and the old, reliable and approved methods such as the crucible, the Tropenas converter and the open-hearth furnace.

It is clear, however, that any method used in the foundry must be able to compete with other processes, and it might, therefore, prove interesting to discuss the various points brought up by Mr. Rennerfelt.

Economy

Authorities in the United States agree that although cheap energy is one of the main factors in the economical production of electric steel, it is not of such great importance. W. L. Morrison, before the convention of the American Foundrymen's Association last September, stated:

"Steel can be melted and refined in the electric furnace for from $27 to $35 per ton in the ladle, depending on the power cost, cost of materials and the care of the melter. The electric furnace to-day is somewhat overrated by claims that it is especially adapted to all foundry use; that its operation is very simple and easily mastered, and that the hottest kind of metal is obtained, so that low-carbon steels can be poured in the thinnest sections. All these statements are more or less true, but should be investigated by the foundryman, so as to avoid disappointment after installation.

"There are some installations of electric furnaces which have been made during the past two years, which did not come up to the expectations of the foundryman, and were either abandoned or operated in a half-hearted way. An electric furnace installed with the idea that one heat a day will pay its way is disastrous to the foundry. The electric furnace, while adapted to foundry work under certain conditions, should not be considered as an ordinary piece of apparatus. It is very delicate or at least certain parts are, as one finds out in practice. A careless melter can add $5 to $15 to the cost of a heat from electrode breakage by neglecting to raise his electrodes during the removal of slag, or when charging the furnace.

"In the charging of the furnace a certain amount of care must be exercised to insure prompt electrical contact and smooth working of the electrodes. I think the electric furnace involves more good common sense and observation than any of the well-known methods of producing steel. It is very easy to lose an hour or even three hours by poor electrical contact at the offset, due to either poor charging or poor selection of scrap. Those who have had practical experience with the furnace know how aggravating a poor electrical contact is; on the other hand, a short circuit the moment the arc is made and subsequent surges of current are readily overcome by placing a little slag around the electrodes.

"The operation of the furnace and the reactions taking place appear so simple that the ordinary spectator is apt to be misled."

E. B. Clark, who probably has had more experience than any other in this country in the use of electric furnaces for manufacturing steel castings, stated in a lecture before the American Electrochemical Society last April that:

"The cost of production is the final answer from a commercial standpoint, and this depends not only upon the market for the intended output, but upon the available supply of steel-making materials, and upon the availability of a satisfactory and sufficiently cheap source of electrical power. In passing it might be observed that this question of electric power supply is generally not so serious as might at first appear. In the first place, there are many locations where a sufficient amount of fairly cheap electric power may be purchased, and in the second place, the item of power is not often of supreme importance.

"There are other elements entering in the production of electrically refined steel which have a far greater influence on the cost of production than is generally credited. The most important of these is experience. It should be understood clearly that the electric furnace is a more delicate apparatus than any of the usual furnaces employed. It is more difficult to handle and its operation offers more likelihood of mishaps. Electric furnace operation has not yet been reduced to standard practice. Melters familiar with its operation are scarce and difficult to find."

Speaking about low power consumption, Mr. Clark has this to say:

"As a matter of fact, claims for low power consumption by any furnace should be received skeptically. It is a fact that the power consumption of any electric furnace depends somewhat upon the efficiency of the furnace, but it also depends to a far greater extent upon the thoroughness of the heat insulation, for, after all, the only heat which is lost is that which escapes by radiation or conduction. That which goes out in the slag, or in the steel, depends not upon the efficiency of the furnace, but upon its mode of operation. Where a high degree of refining is necessary, slags must be taken off at the cost of power consumption. Where the furnace must be operated with considerable time between the heats, heat is escaping rapidly during that idle time.

"Where heats must be held in the furnace, or melted slowly, to meet a definite schedule, a high power consumption must be expected. For these reasons it appears that the claims for low power consumption of certain furnaces are practically valueless from an operating standpoint. The conditions of operation, rather than the type of furnace, are what control the power consumption, though, of course, the construction of the furnace, as regards heat insulation, does have some influence."

Ease of Operation

As far as operation of electric furnaces is concerned, it is the general belief that considerable care and knowledge are required, and to cover this point to some extent we can continue to cite Mr. Clark's paper:

"To attempt an answer as to what type of furnace is best is as unsatisfactory as to make general comparison between electric furnaces and other furnaces. If we could accept at face value the statements of a number of men interested in the development of certain electric furnaces, we could easily believe that as soon as a foundryman has installed an electric furnace (provided he installed the right one) his troubles would be at an end. As a matter of fact, he is apt to find that they are just beginning. In the first place, unless the design of the furnace has been thoroughly tried out in practice, it will certainly have to be modified considerably from the designer's ideas. In the second place, the user will certainly find the furnace to be a more delicate piece of apparatus than he had anticipated. He will find that while he can make steel of a very high quality, he can also make, without difficulty, much steel of a very low quality. If there are in the society some men who have been using electric furnaces for the production of castings or special steels, they will have no difficulty in recognizing these remarks from one who has had such experience.

"It so happens that the speaker's experience has embraced not only a study in this country and Europe of the design and operation of a number of different types of furnaces, but has embraced the actual operation of two typical types of furnaces for the production of steel castings. The investigation as to which general type of furnace is best led in my case, as in that of most others, to much confusion of ideas. It is so evident that each type has certain advantages and disadvantages, and so impossible accurately to gauge the proper importance of the various advantages and disadvantages, that one cannot reach a conclusion as to which type of furnace is best wih confidence in his conclusion. Perhaps the only way to learn is to try them all. As a matter of fact, the speaker has already tried two, and feels that he has not yet decided the question."

Refining Possibilities

It is granted that as a refining medium the electric furnace cannot be excelled, but whether such extensive refining as indicated by Mr. Rennerfelt is commercial is very doubtful, for such reasons as were already expressed above (number of slags, meeting definite pouring schedules, etc.).

At the April meeting of the Electrochemical Society Mr. C. A. Hansen pointed out that:

"Current opinion has it that one of the advantages of the electric furnace is that it can work up any sort of charge. While this may be true quite often, it is not well to base estimates of the cost of molten electric furnace steel upon the usual published furnacing costs, and upon the local prices for stove scrap and similar materials. Probably every operator of an electric furnace has at one time or another run off heats from charges composed of stove scrap or its equivalent, and little need be said for or against such a procedure."

On the other hand, we all know that in the electrical industry, for considerations of permeability, steel must be of as low carbon content as can possibly be obtained. In the Tropenas Converter such low carbon can be attained at *no additional cost*, and almost pure iron can be cast inasmuch as at the end of the usual converter operation the steel contains only 0.09 per cent carbon, 0.02 per cent silicon and traces of manganese. To cast such metal high temperatures are required and the converter process presents the only means of obtaining such results commercially. Mr. C. A. Hansen says on the subject:

"With the electric furnace maintenance costs increase rapidly as the carbon contents of the product is brought down, and quite contrary to current opinion, it is not economical to turn out 0.10 carbon steel castings, although it is perfectly possible to do so."

Other authorities agree as to the difficulties encountered in the electric furnace when producing low carbon steels.

Loss from Oxidation

It is true that converter loss runs usually about 7 per cent higher than that of the electric furnace, but the conclusions drawn by Mr. Rennerfelt are quite erroneous. The fact that there is a higher loss in the converter does not affect the chemical analysis of the metal. At the end of the blowing operation silicon, manganese and carbon are practically burned out so that there can be no undesirable uncertainty of analyses, inasmuch as the very elements characterizing the steel are almost absent.

This is even one of the great points of superiority of the Tropenas converter over the electric furnace. When blowing is stopped, the analysis of the bath in the converter is almost constant so that *any* composition of steel can be obtained by the additions of the proper elements.

The converter practice which has been referred to by Mr. Rennerfelt must have been very poor, inasmuch as in this country we consider 18 per cent the maximum (instead of 28 and 33 per cent) which includes both cupola and converter losses. As far as temperature of metal is concerned, we believe that if higher ranges were attained in the electric furnace than are obtained in this country under ordinary practice in Tropenas converters, the life and stability of electric furnaces would be considerably endangered.

The best proof to the effect that converter metal does not cause scrap on account of low temperature is that all converter foundries in this country cannot make enough scrap and have to buy from 15 to 20 per cent of their actual cupola charges. As a matter of fact, one of the hardest things to find in an American converter foundry is home-made scrap.

In American practice we operate converters with lower silicon and higher manganese contents in the charge without injury to our linings. This is probably due to the elimination of brick and the substitution of ganister for linings after considerable study and experimenting.

Supply of Raw Material

Most of the electric furnaces operating in this country are run on an all-scrap basis in order to eliminate delicate and costly refining. All-scrap melting is, in our opinion, the only commercial course open to the electric furnace for the reason that the very smallness of most steel foundries does not allow the hiring of expensive melters. If this line of least resistance is followed, the electric furnace will encounter conditions similar to those of the old crucible furnace days. The law of supply and demand enters here into consideration, and it is useless to discuss the point, because as long as a market is created for steel scrap, the prices are bound to rise, and as the general opinion prevails that for the purpose of producing steel castings the electric furnace will be used as a scrap melter pure and simple, such market was created by the introduction of the electric process.

Reliability

In the light of the fifty analyses of consecutive blows published in our previous article and considering also the fact that this record is only a part of a series of over 22,000 similar operations, it is hard to conceive how the Converter process could be called a "hit or miss" method. This same point was raised when the Tropenas converter was brought out, and we always

refer with pleasure to the tests which the British Admiralty conducted in order to determine whether the open hearth process was more uniform and more reliable than the Tropenas converter.

The result of these tests cannot be published, but the fact that several Tropenas converters were installed after the tests were completed speaks louder than words.

To the practical foundryman it is perfectly clear that wherever the personal equation does not enter into consideration, greater regularity and consequently greater reliability can be expected. As stated in our previous article, converter operation hinges around good cupola practice. There is no simpler furnace to operate than a cupola, the practice has been reduced to definite standards, so that the operation of the Tropenas converter itself is purely mechanical. The best proof of this statement is found in the very lack of understanding on the part of the average converter operator, of the actual reactions taking place during the blowing.

Suitability of Process to Product

Mr. Rennerfelt cites an article published in *The Iron Age* of March 27, 1913, by Mr. E. F. Lake, in which Tropenas converter steel castings are not treated in a very complimentary way. We were tempted, at the time the above-mentioned article appeared, to take up the cudgel for the converter castings, but the statements made were so evidently the product of great enthusiasm for a new method that we disregarded their being at variance with actual facts.

To anyone who has followed the development of the steel castings industry in this country it is known that the Tropenas converter has steadily displaced the crucible process, and we venture to say that the days are not far off when the number of crucible steel foundries manufacturing steel castings will be counted on the fingers of one hand.

The lack of control over carbon contents gave the crucible process its death blow, and the only surprise which can be evinced is that the other inconveniences inherent to this process had not forced its users to a change long ago.

Former crucible furnace men, who are today strong Tropenas converter enthusiasts, tell us that their product is today so superior to that they used to turn out that they are able to satisfy clients which the crucible had lost to them.

It will be of interest to note that in the automobile industry, where the utmost care has been exercised in the drawing up of rigid specifications, over 95 per cent of the steel castings used are the product of the Tropenas converter. It will also be of further interest to note that at least two large motor truck manufacturers who had found it to their advantage to purchase steel castings from one of the best electric furnace steel producers in Europe are now using castings made in the Tropenas converter exclusively.

We do not want the reader to infer from the above that steel castings produced in the electric furnace are not of the highest grade, because under good management the electric furnace will produce a superior casting, but under ordinary conditions the electric steel casting will suffer the disease of all things that are superior, namely, it will be too expensive for the quality achieved.

This leads us to remember the remark of one of our Boston friends who, when called upon to purchase an electric furnace instead of a Tropenas converter said, "Why buy silk stockings when cotton ones will do?"

Flexibility of Process

We are afraid that Mr. Rennerfelt's suggestion to use mixers in connection wih the electric furnace in order to increase the latter's range, is not very practical. The primary superheating of the steel or the suggested use of thermit would only add to the cost of a product which is already in great danger of being too expensive, and our suggestion would be to use the electric furnace within the range of its own capacity and make the best of a process which has no flexibility.

The pouring of castings weighing 3 or 4 times the rated capacity of any Tropenas converter is the simple result of speedy operation which is not and will never be met by any electric furnace.

It might be said in passing that contrary to the usual belief, Tropenas converters are not lined with bricks but with ganister, which accounts for the ease with which 3 operations can be made in an hour, 20 and even 25 in an ordinary working day, and from 36 to 40 without need of repairs.

Segregation of Steel Castings

If the leading authorities were to be consulted today regarding the order in which the various metalloids will segregate in steel, a goodly number of volumes would be filled with dissenting opinions. The writer's contention was based on the opinion that the electric furnace can be used commercially only as a steel-scrap melting device, and in such a case the final product will always be higher in carbon than the scrap used, because the analysis of the average steel scrap shows carbon contents which are too low for steel castings purposes.

The resulting "home scrap" made of gates and risers will produce a "building up" of carbon similar to that which is claimed to occur for phosphorus, sulphur and copper in the converter process.

If, according to certain authorities, carbon being present in larger quantities in steel than any other metalloid, segregates first then segregation will be greater in the electric process; if sulphur and phosphorus segregate first, the segregation will be greater in converter steel.

The above, however, is important only in the manufacture of ingots. In the production of steel castings such interest is not surprising when originating from the Tropenas converter, the bodies of metals are so small that segregation need not be considered.

Market for Various Steel Castings

We must thank Mr. Rennerfelt for the tribute paid by him to the various manufacturers interested in the production of better steel castings. The fact that inquiries are being made about electric furnaces proves without a doubt that interest has been aroused, but such interest is not surprising when originating from a country where it is almost a cult to produce "the best in the world."

One fact, however, must not be lost sight of, namely, that it is one thing to manufacture a product and still another to sell it.

American manufacturers are open to conviction. They are using old and tried methods for producing steel castings and we are sure that any medium of increasing quality will be received with favor. Its general use, however, will remain problematical as long as increased cost of production is not commensurate with betterment of quality.

Tropenas Converter Co.,
New York City.

The Nevada State Mining Laboratory, now organized as a department of the Mackay School of Mines, has for its object the free analysis of ores, rocks and minerals taken from within the boundaries of Nevada by citizens of the state. In 1914 assays were made for 804 persons who sent in 1631 samples from 248 localities. A total of 6533 determinations were made on these samples.

Presentation of the Perkin Medal to Edward Weston

The ninth impression of the Perkin Medal was presented to Dr. Edward Weston, president of the Weston Electrical Instrument Company of Newark, N. J., on the evening of January 22, 1915, in a joint meeting of the New York sections of the Society of Chemical Industry, the American Chemical Society, and the American Electrochemical Society. The medal had been awarded to Dr. Weston unanimously at the meeting last month of the Perkin Medal Committee, consisting of representatives of the above three and other allied chemical societies.

The meeting of January 22 was very well attended, many ladies being present, and lasted till almost midnight. It was called to order by the chairman of the New York Section of the Society of Chemical Industry, Dr. G. W. THOMPSON. The Perkin medal was presented to Dr. Weston by Dr. Charles F. Chandler, Senior Past President of the Society of Chemical Industry in America.

Yours Sincerely
Edward Weston

DR. CHANDLER'S PRESENTATION SPEECH

Dr. CHARLES F. CHANDLER, in his presentation address, spoke of the early life of Weston. Edward Weston was born on May 9, 1850, at Bryan, near Oswestry, Shropshire, England. While he was still young his father moved to Wolverhampton in Staffordshire, where he was educated under private tutors, receiving his first instruction in physics and chemistry.

By this time even he had already manifested a great taste for science and also for experimenting and occupying himself in the use of mechanical tools. His parents desired him to select some well established profession for his life work, and they first placed him with a dentist, but this did not suit his tastes. Then they tried him with two physicians, Dr. K. H. and J. E. Colman. He decided that he could stand surgery, but he did not like medicine. But these physicians exercised a most beneficial influence upon him because they were broad-minded scientific men, both of them in the habit of lecturing on scientific subjects and illustrating them by experiments. So Weston's interest in chemical, metallurgical and electrical subjects, which he had developed while he was still a boy, was greatly increased by his association with these men.

While still only sixteen years of age he delivered an illustrated lecture on electricity, performing the experiments with apparatus which he had himself constructed. The fact soon become apparent to him that he had no taste for the practice of medicine, so he determined to leave home and strike out for himself. Armed with some letters of introduction, he prepared to go to London, but on thinking the matter over he finally concluded to go to America and make a career there, which he certainly has done. He arrived in New York in May, 1870, with his modest library and outfit of chemical and physical apparatus, and a very limited amount of cash and a very simple wardrobe.

He began at once to look for employment, tramping daily through New York, Long Island and everywhere where he thought chemical operations were carried on. Finally he ran across the small concern of William H. Mardock & Co., manufacturers of photographic chemicals and dealers in photographic supplies and apparatus. Here he made his beginning, manufacturing pyroxyline and a general line of photographic chemicals, staying about a year. During this period and later, for about three years, he assisted Professor Charles S. Stone, Professor of Chemistry, at the Cooper Union.

He watched the daily papers and one day saw an advertisement for a man having some chemical and electrical knowledge, especially electroplating. He answered this advertisement and the next morning a man came to the store and inquired for Weston. This man was a representative of William H. Belden, president of the American Nickel Plating Company. After a short interview Mr. Belden proposed to engage him at once, but he felt that he could not leave his employers so suddenly, and arranged to continue his position with Mardock & Co. for a fortnight and to work nights in Belden's establishment. He found that the nickel-plating works were in very poor shape, especially the galvanic batteries employed as a source of electricity. He went to work immediately, put the batteries and other things in order and at the end of two weeks everything was working satisfactorily.

When Dr. Weston took his position with the American Nickel Plating Company he made most careful investigation into all the details of the art, and made many improvements in these details, by which he improved the quality of the coating, secured great economy in nickel, and greatly reduced the time required for plating, and particularly succeeded in the preparation of the surface to which the nickel was to be applied and in the polishing of the nickel coating. He also discovered a dip which could be conveniently used for removing nickel from damaged goods in order to coat them again. With these improvements the business of the company increased very rapidly and they nickel-plated the greatest variety of articles from a bunch of keys to a fire engine.

Owing to dissensions among the stockholders of the company, the business was finally given up. Weston then went to the Silver Nickel Plating Company about the middle of 1872. He found the process they were carrying on was entirely unsatisfactory and turned the place into a nickel-plating business. He soon left the company, however, and was appointed consulting expert by the Commercial Printing Telegraph Company, operating the patents of Foot and Randall. The company was soon bought out by the Gold and Stock Telegraph Company.

Dr. Weston then formed a partnership with a Mr. Harris under the firm name of Harris & Weston for general plating business; copper, brass, nickel, silver and gold. Here he built, in the latter part of 1872, a dynamo as a substitute for batteries in electroplating. This greatly increased his business, so he enlarged the plant and finally moved to Center Street. Here he built another dynamo, larger and somewhat different. Then he built a third dynamo for a manufacturing firm in Newark. At this time he withdrew from the plating business and made an arrangement with the Newark firm to build a dynamo for electroplating and made about twenty of them. They were so expensive, however, that they could only be used by large concerns. He started to design a simpler and cheaper machine, but the firm decided to give up the business. A new firm, Stevens, Robbins & Hayville, bought them out and Weston went into partnership in order to develop a new nickel anode which he had invented and for which he obtained his first patent in 1875.

Born in 1850, Weston was twenty years of age when he came to America in 1870, and he took out his first patent in 1875 at the age of twenty-five. The record of his varied

experience, his efforts and successes for the first five years of his working life is certainly very remarkable, and gave promise of all that he has accomplished since. He has taken out over 350 patents for his various inventions, and has made radical improvements in several arts. Besides that, a great deal of his work has involved the most patient and careful scientific investigations, often of microscopic accuracy, and has contributed largely to the advance of scientific knowledge and theory.

It would give me a great deal of pleasure to explain to you in detail the great variety of subjects which Dr. Weston has investigated and developed during the forty years since he took out his first patent, but as I am to be followed by Dr. Baekeland, Dr. Hering and by Dr. Weston himself, I must deny myself the pleasure.

In 1903 McGill University conferred upon Mr. Weston the degree of LL.D., in 1904 the Stevens Institute of Technology bestowed the degree of D. Sc., and in June, 1910, Princeton University conferred the same degree.

Edward Weston, Doctor of Laws and Doctor of Science, my dear friend: It gives me the greatest pleasure as the representative of the affiliated chemical and electro-chemical societies to place in your hands this beautiful token of appreciation and affection of your fellow chemists.

Dr. Weston, after receiving the Perkin medal, expressed his thanks in a felicitous little speech, in which he gave reminiscences of his first meeting with Dr. Chandler many years ago.

Dr. Baekeland's Speech

Dr. Leo H. Baekeland in his address on "Edward Weston's Inventions" said that Edward Weston's pioneer work was not easy to describe in a few words, as his restless inventive activity has been spread over so many subjects, has intertwined so many interlocking problems—electrodeposition of metals, electrolytic copper refining, construction of electric generators and motors, illumination by arc and incandescent lamps, and the manufacture of electrical measuring instruments. An impressive list of subjects, but in every one of those branches of industry, Weston was a leader.

But why was Weston able to overcome difficulties which seemed almost unsurmountable to his predecessors and coworkers in the art?

The answer is simple: He introduced in most of his physical problems a chemical point of view—a chemical point of view of his own; a point of view which was not satisfied with general statements, but which went to the bottom of things. He did not get his chemistry wholesale as it is dispensed in some of our hot-bed-method educational institutions. He had to get at his facts piece-meal, one by one, adjust them, ponder over them, collect his facts with much effort and discrimination; he did not acquire his knowledge merely to pass examinations, but to use it for accumulating further knowledge.

It seems rather fortunate for him that one of the first employments he got in New York was with a chemical concern which made photographic chemicals. This was the time of the wet-plate, when photographers made their own collodion, their own silver bath, their own paper. Whoever went through those delicate operations, knew the difficulties, the uncertainties which were caused by small variations in the composition of chemicals or in the way of using them. Photochemistry is excellent experience for any young chemist who is disposed to generalize too much all chemical reactions by mere chemical equations. Whoever has to deal with those delicate chemical phenomena, which occur in the photographic image, knows that many unforeseen facts can not easily be accounted for by our self-satisfying but often superficial generalizations of the text-books.

Weston's tendency to observe small details in chemical or physical phenomena led him to improve the art of nickel-plating and electrolytic deposition of metals to a point where it entered a new era. When he undertook the study of the difficulties in this art, he took nothing for granted, but by close observation, he succeeded in devising methods not only of increasing the physical texture of the deposit, but for improving enormously the speed and regularity with which the operations could be carried out; all these improvements are now embodied in the art of electrotyping, nickel-, gold-, and silver-plating.

At this time, attempts had already been made for the commercial refining of copper by means of the electric current. But this subject was then in its first clumsy period, far removed from the importance it has attained now among modern American industries. Here again, Weston brought order and method, where chaos reigned. His careful laboratory observations, harnessed by his keen reasoning intellect, established the true principles on which economic, industrial, electrolytic-copper-refining could be carried out. Dr. James Douglas (Commencement Address, Colorado School of Mines, *Metallurgical and Chemical Engineering*, Vol. XI, No. 7, July, 1913, page 377) referred to this fact in a recent address:

"I suppose I may claim the merit of making in this country the first electrolytic copper by the ton, but the merit is really due him (Weston) who in this and innumerable other instances, has concealed his interested work for his favorite science and pursuits under a thick veil of modesty and generosity."

The whole problem of electrolytic refining, when Weston took it up, was hampered by many wrong conceptions. One of them was that a given horsepower could only deposit a maximum weight of copper, regardless of cathode- or anode-surface. This fallacious opinion was considered almost an axiom until Weston showed clearly the way of increasing the amount of copper deposited per electrical horsepower, by increasing the number and size of vats and their electrodes, connecting his vats in a combination of series and multiple. The only limit to this arrangement being the added interest of capital and depreciation on the increased cost of more vats and anodes, in relation to the cost of horsepower for driving the dynamos.

The electrodeposition of metals forced Weston into the study of the construction of dynamos. Until then, the electric current used for nickel-, silver- and gold-plating, as well as for electrotyping, was obtained from chemical batteries. Weston says that it was almost a hopeless task to wean electroplaters from these cells to which they had become tied by long experience and on the more or less skilful use of which they based many of the secrets of their trade.

If the dynamo as a cheap and reliable source of electric current was advantageous for nickel-plating, it became an absolutely indispensable factor for electrolytic copper refining. At that time, the dynamo was still at its very beginning, some sort of an electrical curiosity. It had been invented many years before by a Norwegian, Soren Hyjorth, who filed his first British patent as far back as 1855. Similar machines had been built both in Europe and America, but little or no improvement was made until Weston, in his own thorough way, undertook the careful study of the various factors relating to dynamo efficiency.

Dr. Baekeland then sketched Weston's work in dynamo design, for which he worked out the first patent in 1876, and mentioned that the first practical application of electric power transmission for factory purposes in this country was in the Weston factory in Newark.

Weston's work in illumination was sketched next. Weston started the manufacture of arc-lamp carbons in this company which he continued until 1884. To improve the color he invented what is now called the flaming arc.

In relation to this invention, it is interesting to quote the following extract of the specifications from his United States Patent 210,380, filed November 4, 1878: "This rod or stick may be made of various materials—as, for example, of so-called lime glass, or of compounds of infusible earths and metallic salts, silicates, double silicates, mixtures of silicates with other salts of metals, fluorides, double fluorides, mixtures of the double fluorides, fusible oxides, or combinations of the fusible oxides with the silicates—the requirements, so far as the material is concerned, being that it shall be capable of volatilization when placed on the outer side of the electrode to which it is attached, and that its vapor shall be of greater conductivity than the vapor or particles or carbon disengaged from the carbon electrodes. The foreign material added to the carbon may be incorporated into the electrode by being mixed with the carbon of which the electrode is composed, or it may be introduced into a tubular carbon; but I have found it best to place it in a groove formed longitudinally in the side of the electrode, as shown."

In his endeavors to make the electric incandescent lamp an economic possibility, we see him introduce over and over again, chemical methods and chemical considerations. He first tried to utilize platinum and iridium, and their alloys, which he fused in a specially constructed electric furnace, devised by him, antedating the furnace described by Siemens. This is probably the first electrical furnace, if you will except the furnace which Hare used in his laboratory in Philadelphia.

But these platinum metals showed serious defects aside from their high cost, and by that time, Weston had become so familiar with the properties of good carbon that like

other inventors, he became convinced that the ultimate success lay in that direction.

Dr. Baekeland then sketched Weston's work on incandescent lamps. The fatal defect of early lamps was structural lack of homogeneity. There would be points with a high resistance and these would burn out.

Weston tried to solve this difficulty by means of his chemical knowledge. He remembered that as a boy, when he went to visit the gas works to obtain some hard carbon for his Bunsen cell, this carbon was collected from those parts of the gas retort which had been the hottest, and where the hydrocarbon gas had undergone dissociation leaving a dense deposit of coherent carbon.

In this chemical phenomenon of dissociation at high temperature, he perceived a chemical means for "self-curing" any weak spots in the filament of his lamp. The remedy was as ingenious as simple. In preparing his filament, he passed the current through it while the filament was placed in an atmosphere of hydrocarbon gas, so that in every spot where the temperature rose highest on account of greater resistance, brought about by the irregular structure of the material, the hydrocarbon gas was dissociated and carbon was deposited automatically until the defect was cured, with the result that the filament acquired the same electric resistance over its whole length.

But this invention, however, brilliant, did not limit his efforts. He had become imbued with the idea that the ideal filament would be an absolutely structureless, homogeneous filament, with exactly the same composition and the same sections throughout its whole length. He reasoned that such a filament could not be obtained from any natural products, neither from paper nor bamboo, but that it had to be produced artificially in the laboratory from an absolutely uniform, structureless chemical substance. After various unsuccessful attempts, he finally secured this result by applying his old knowledge of the days when he used to make collodion. He produced a homogeneous, structureless transparent film of nitrocellulose by evaporating a solution of this material in suitable solvents. As he could not carbonize this film on account of the well-known explosive properties of so-called "gun-cotton," he obviated this difficulty by eliminating the nitrate group of the molecule of cellulose-nitrate by means of ammonium-sulphydrate. This gave him a flexible, transparent sheet, very similar in appearance to gelatine; this material he called "tamidine." Such films could be cut automatically with utmost exactitude, producing filaments of uniform section, which then could be submitted to carbonization, before fastening them to the inside of the glass bulb of the incandescent lamp.

It is interesting to note here that the modern tungsten lamp, in all its perfection, made of ductile tungsten, is after all, the fullest development of the principle of an entirely structureless, homogeneous chemical filament. The tungsten-filament can stand much higher temperatures than carbon and this property gives it higher lighting efficiency, but the former tungsten filaments of a few years ago, which had a granular structure, had the same defect as the earlier carbon lamps, namely, a non-homogeneous texture and correspondent short life.

While Weston was wrestling with all his electrical problems, and more particularly with the construction of dynamos and motors, he was handicapped continuously by the clumsy and time-consuming methods of electrical measurements which were the best existing at that period. Up till then, these methods had been found good enough for physical laboratories, where the lack of accuracy did not result disastrously in hitting the pocket of the manufacturer, or where time—abundant time—for observations and calculations was always available. But progress in the electrical industries lagged behind the delay and uncertainties caused by electrical measurements.

So Weston was compelled to invent for his own use a set of practical electrical measuring instruments. It was not long before some of his friends wanted very badly duplicates of his instruments; before he knew it he was giving considerable attention to the construction and further development of these instruments.

Just about this time the electric light and dynamo construction enterprise entered into a new period where they began to develop in large unwieldly commercial organizations, requiring public franchises and which had to be backed by vast amounts of new capital. In its boards of directors business men or financial men and corporation lawyers became paramount factors and eclipsed in importance the technical or scientific men, who, in earlier days, had almost exclusively contributed to the development of the art.

Following his natural inclinations, Weston soon abandoned his former business connections in order to entrench himself in a field where individuality, science and technology were of almost unique importance, and which he could develop without the necessity of incurring financial obligations beyond what he could master personally. Thus he dropped his connections with the electric light and dynamo enterprises and we see him now, heart and soul, in another new industry which he created—the art of making accurate, trustworthy and easy-to-use electrical measuring instruments. Did he foresee at that time that this art would attain the magnitude to which he has brought it to-day? Did he dream that his early modest shop was to develop into one of the most remarkably equipped factories in the world; an institution which seems the embodiment of what industrial enterprises may look like in future days, when scientific and liberal minded management will have become the rule instead of the exception.

In his factory in Newark, Weston seems to have instilled some of his own reliability and accuracy in the minds of the men and women he employs.

In fact, has it occurred to you that even a man with the widest knowledge and the highest intelligence, who is not scrupulously reliable and careful, who is not the soul of honesty personified, could not make honest and trustworthy measuring instruments nor create reliable measuring methods?

What Stas did in chemistry for atomic weights, Weston did for electrical measuring; he created radically new methods of measurement and introduced an accuracy undreamt of heretofore. Do not forget that his problems were not easy ones. When the British government offered a prize of $100,000 for the nearest perfect chronometer, the problem of a reliable chronometer involved considerably less difficulties and fewer disturbing factors than those encountered in devising and making electrical measuring instruments. But here again, even at the risk of monotonous repeating, I want to impress you with the fact that the success of the methods of Weston was found in almost every case in the application of chemical means by which he tried to solve his difficulties.

When he took up this subject, the scientists, as far back as 1884, accepted implicitly the belief that the definition of a metal and a non-metal resides in a physical distinction; that for metals the electrical resistance increased with temperature, while for non-metals, their resistance decreased with temperature. This was another one of those readily accepted axioms which nobody dared to refute or contest because they were repeated in respectable text-books.

And yet this unfortunate behavior of metals was the greatest drawback in the construction of accurate measuring instruments. Indeed, on account of the so-called temperature coefficient, all measurements had to be corrected by calculation to the temperature at which the observation was made. This seems easy enough, but it was time-consuming and often it is more difficult to make rapid accurate observation of the temperature of the instrument itself. First of all, the thermometers are not accurate, and have to be corrected periodically, and furthermore, it is not an easy matter to determine rapidly the temperature of a coil or instrument. Moreover, by the very passage of the electric current, fluctuating changes in temperature are liable to occur, which would make the observations totally incorrect. All this led to hesitation and slowness in measurements.

Weston wanted to correct this defect, but he was told that the very laws of physics were against his attempts. Before he was through with his work, he had to correct some of our conceptions of the laws of physics; now let us see how he did it:

Weston knew that the favorite metal for resistances was so-called German silver. Strange to say, he was the first one to point out to the Germans themselves that "German silver" is a word which covers a multitude of sins, and that the composition of German silver varies considerably according to its source of supply. The result was that he soon proposed a standard copper- and nickel- and zinc-alloy containing about 30 per cent. of nickel, and which had a resistance of almost twice that of ordinary German silver and a much lower temperature co-efficient.

Not satisfied with this, he took up the systematic study of a large number of alloys. The first batch which he undertook to study amounted to more than 300 different alloys. Since that time, he has considerably increased this number, and is still busy at it. Everyone of these alloys he made himself in his laboratory, starting from pure materials, and controlling the whole operation from the making of the alloy to the drawing of wires of determined size. By long and repeated observations, on which many years have been consumed, he was able to determine the electrical behavior of each one of these alloys at different temperatures.

After awhile, he began to observe remarkable properties

in some manganese alloys he compounded. He managed to produce an alloy which had sixty-five times the resistance of copper. But getting bolder and bolder, he strove to obtain an alloy which had no temperature-coefficient whatever. He not only succeeded in doing this, but finally, produced several alloys which had a *negative* temperature-coefficient. In other terms, their resistance, instead of increasing with rise of temperature, decreased with increasing temperature. He also showed that the resistance of these alloys depended not only on their composition, but on certain treatments which they undergo, for instance, preliminary heating. And since that day, the physicists have had to bury their favorite definition of metals and non-metals. The present generation can hardly realize what this discovery meant at that time. I could not better illustrate this than by reminding you of the fact that in 1892, at the meeting of the British Association for the Advancement of Science, where it was urged to found an institution similar to the Deutsche Reichsanstalt, Lord Kelvin said in his speech:

"The grand success of the Physikalische Reichsanstalt may be judged to some extent here by the record put before us by Prof. von Helmholtz. Such a proved success may be followed by a country like England with very great profit indeed. One thing Prof. von Helmholtz did not mention was the discovery by the Anstalt of a metal whose temperature co-efficient with respect to electrical resistance is practically nil; that is to say a metal whose electrical resistance does not change with temperature. This is just the thing we have been waiting for for twenty or thirty years. It is of the greatest importance in scientific experiments, and also in connection with the measuring instruments of practical electric lighting, to have a metal whose electrical resistance does not vary with temperature; and after what has been done, what is now wanted is to find a metal of good quality and substance whose resistance shall diminish as temperature is increased. We want something to produce the opposite effect to that with which we are familiar. The resistance of carbon diminishes as temperature increases; but its behavior is not very constant. Until within the last year or so nothing different was known of metals from the fact that elevation of temperature had the effect of increasing resistance. The Physikalische Anstalt had not been in existence two years before this valuable metal was discovered."

Then followed this colloquy:

"Prof. von Helmholtz—The discovery of a metal whose resistance diminished with temperature was made by an American Engineer.

Prof. Ayrton—By an Englishman—Weston.

Lord Kelvin—That serves but to intensify the position I wished to take, whether the discovery was made by an Anglo-American, an American Englishman, or an Englishman in America. It is not gratifying to national pride to know that these discoveries were not made in this country."

The misinformation of Kelvin was due to the fact that after the Weston patents had been published, his alloy was called *manganin* in Germany, and quite some publicity had been given to its properties with scant reference to its real inventor, an occurrence which, unfortunately, is not unfrequent not only among commercial interests but in technical or scientific circles as well.

No less important was the invention of the Weston cell, which in 1908, by the international commission for the establishment of standards of electrical measurements, has become the accepted universal practical standard for electromotive force. Here again, this physical standard was obtained by chemical means. . . .

"Dr. Weston assures me that he has succeeded in making his alloys to show only a change of one-millionth for a variation of 1 deg. C. The metallic alloys he discovered are used practically in nearly all kinds of electrical measuring instruments throughout the world. Weston instruments and Weston methods are now found in all properly equipped laboratories and electrochemical establishments of the world. On a recent trip to Japan, I saw them in the University of Tokio, as well as in the Japanese war museum, where their battered remains attested that the Russians used them on their captured battleships. I have worked in several laboratories in Europe equipped with an instrument said to be "just as good" as those of Weston, but in most instances they were imitations of Weston instruments and it was significant that they kept at least one Weston instrument to be used to correct and compare their national product.

"Like many inventors, Weston has been engaged extensively in patent litigation. To uphold some of his rights, he had to spend on one set of patents nearly $400,000, a large amount of money for anybody, but as he told me, he begrudges less the money it cost him than all his valuable time it required—a greater loss to an inventor thus distracted from his work. What is worse, most of this litigation was so long-winded that when finally he established his rights, his patents had aged so much that they had lost, in the meantime most, if not all, of their seventeen years' term of limited existence. And here I want to point out something very significant. In the early periods of his work, between 1873 and 1886, Weston took out over 300 patents. Since then, he has taken considerably less, and of late, he has taken out very few patents, after he became wiser to the tricks of patent infringers.

"Formerly, as soon as he published his discoveries or his inventions, in his patent specifications, he was so much troubled with patent pirates that instead of being able to attend to the development of his inventions, he was occupied in patent litigation. As an act of self-preservation, he has had to adopt new tactics. He now keeps his work secret as long as possible, and in the meantime spends his money for tools and equipment for manufacturing his inventions. In some instances, this preparation takes several years. Then by the time he sends any new type of instruments into the world, and others start copying, he has already in preparation so many further improvements that pretty soon the next instrument comes out which supersedes the prior edition.

"He had to utilize these tactics since he found how impractical it was to rely on his patent rights for protection. That inventors should have to proceed in this way is certainly not a recommendation for our patent system; it kills the very purpose for which our patent laws were created, namely, *the prompt publication of new and useful inventions.*

Dr. Weston's Address

Dr. Edward Weston made a very interesting and thoroughly characteristic address. As he had a cold, he started with a low and hoarse voice, but it grew stronger as he kept on, and he stuck to his subject until he had brought out what he wanted to say. He had no prepared speech, but spoke off-hand. He told delightful reminiscences of his doings with men and customers, how they had to be handled and educated, how early troubles were changed into final successes, and how endless research work had to be kept up to achieve results. This informal way of talking made his speech particularly charming in its personal directness to his audience. But it also deprives us of the privilege of publishing the address now in full. We cannot do better than give a rough outline of his speech at this time.

Dr. Weston said he was glad he had acquired from his work in chemistry that exactness and experience which can only be obtained from chemistry. He had always been together with chemists. He regretted that the specimens of his early chemical and physical work had been packed away in boxes and were therefore not available now.

Dr. Weston first dealt at considerable length with his early work on nickel plating. The public had to be educated and the platers had to learn how to do it. In general there was no difficulty with the solutions themselves. The trouble was mainly in the use of methods that were employed in the deposition of silver, thus overlooking the fact that silver is soft and nickel is hard. Dr. Weston explained in detail what this difference meant and dealt especially with the methods of cleaning and the substitution of chemical for mechanical cleaning.

During this work Weston got impressed with the fact that nickel is hard, and asked himself whether it would be possible to get softer nickel. He found indeed a method of depositing "malleable nickel" that can be rolled. In this connection Dr. Weston discussed at length the problem of single salts versus double salts.

Dr. Weston recited various cases of troubles, especially the fact that when a single salt is used, first a good deposit is obtained, but after a time it loses its white color, gets darker and assumes a green tint and hydrogen is evolved. This is due to the fact that the solution becomes more and more basic. As soon as acid is added, the deposit becomes all right again.

Weston's work on nickel finally led him to the invention of a new nickel anode and a new nickel solution.

From nickel plating Dr. Weston turned in his address to dynamo design. His first dynamos were built for the plating business and again the platers had to be educated. Dr. Weston told amusing instances of what this meant. Of course, the high first cost was the objection. Weston changed and improved the designs many times,

one of his principal objects being to build cheaper machines.

Dr. Weston then discussed his work on the arc lamp. The cost of imported arc lamp carbons was then $1.20 a dozen when delivered here; that was the reason why he started the manufacture of carbons. In his further work he wanted to change the color, but also wanted to get more light per horsepower. Further he wanted to steady the arc. This led him to the invention of the flaming arc.

When he turned to incandescent lamps, the "subdivision of light" was under considerable discussion. With arc lamps the problem was mechanical, one of regulation. With incandescent lamps a very complicated chemical and mechanical problem was to be solved, and the chemical problem was very severe.

The total resistance of the lamp filament must have a uniform value in all lamps. But this is not enough, since it is necessary that the resistance be uniform all along the length of the filament. In the early filaments, for instance, those made from paper, this was not the case, the fibres being arranged crosswise in all directions. The filament would have high-resistance spots which would burn through. Weston solved this problem by heating the filaments electrically in hydrocarbon vapor whereby a deposit of carbon would form faster on hot spots than elsewhere. This method solved two problems. One was to get the resistance uniform all along the length. The second was that by carrying this operation on long enough it was possible to give to the filament exactly the desired total resistance.

At this point of the address the fighter in the man Weston showed himself in a very characteristic and interesting manner when he discussed the invention of this chemical control of resistance and the fact that the courts had ruled against him in this case.

But the fundamental problem of getting a perfectly uniform structureless filament was later solved by Dr. Weston in another way by extended chemical research. (See Dr. Baekeland's paper above.)

Dr. Weston then gave a review of his work on alloys, starting with German silver and then extending to many hundreds of different alloys. The chief object of this research was to get alloys with the desired resistivity and temperature coefficient for measuring instruments. Manganese is the chief resistance-giving element, nickel comes next. But chemical composition is not everything, since the temperature coefficient depends also on the heat treatment, whether the wire is hard-drawn or annealed. For each alloy it was, therefore, necessary to find the correct heat treatment. This was illustrated in an interesting way by curves exhibited in diagrams on the wall.

Dr. Weston finally spoke briefly of the invention of his standard cell and how he came to use cadmium sulphate.

Dr. Hering's Address

The final address on the program was by Dr. CARL HERING on "Some of Dr. Edward Weston's Achievements in the Field of Electricity."

It is not an exaggeration to say that the rapid development of the electrical industry is in no small part due to the direct-reading electrical measuring instruments which he contributed to the art, and which were of such a high order of accuracy, constancy, reliability, portability and simplicity of application, that it became not only possible but even quite easy to make really reliable measurements, whereby progress in the electrical industries was greatly facilitated. It may be said that the whole space of a room of a laboratory equipped with instruments, has now been reduced by him to a couple of coat pockets, in which the instruments for such measurements may now be carried.

Having myself been engaged in electrical work in that early and trying period when measuring instruments were so sorely needed, as so much of importance had to be discovered by measurements of currents and voltages, and when all but the crudest of these measurements were tedious, difficult, complicated and unreliable, and were generally limited to the use of the laboratory galvanometer, I can personally vouch for the statement that the advent of the Weston instruments marked a turning point in the development of the electrical industry.

More than that, it was a matter of even national interest, for prior to that time the "precision" instruments (in name though not in fact) were imported from abroad. Europe was ahead of America, but now Weston has turned the tables, Europe imports large quantities of these instruments from us. Some years ago, in a visit to the German Reichsanstalt where some of the best research work in the world was being done with the best instruments the world could produce, I noticed, with no little national pride, that Weston instruments, made in America, were in universal use there, and this, in that one of all the European countries which prided itself most for its development of the instrument art.

He early realized that in the successful manufacture of many of the articles used in the electric industry, especially when made on a large scale, such as incandescent lamps, it was essential that reliable and accurate electric measurements be made quickly and by inexperienced labor; he argued that such measurements should be as easy to make as those with the foot rule and the balance. Though considered utopian in those early days, he persisted and finally succeeded in accomplishing it; the accurate measuring of amperes and volts became as simple as reading the dial of a spring balance, and the accuracy and reliability greatly exceeded it. Indeed it may be justly said that he created the art of practical electrical measurements in the industries, with direct reading, portable instruments requiring no trained experience, to a degree of accuracy equal to and often exceeding that formerly obtained with far more complicated apparatus in laboratories, by skilled and experienced men.

One of the essential factors in making such rapidly repeated measurements in the manufacturing industries, was the avoidance of having to make the troublesome correction calculations, such as those due to changes of temperature. As existing metals and alloys were very inadequate in this regard, for resistance materials, on account of their temperature corrections, Dr. Weston, with the determination, persistence and indefatigability which are so characteristic of all his work, and with rare courage in attacking especially difficult problems, set himself the task of finding something better, and as usual he succeeded, giving to the world the alloy now known as manganine, a copper, manganese, nickel alloy, which combined the two very desirable features of a very small temperature coefficient and a high resistivity. The importance of this alloy is shown by the fact that it is now used and adopted internationally. Though the Germans for a time claimed priority in its discovery or invention, they seem now to give him the credit, even to the extent of suggesting calling it "Westonine."

Having succeeded in what he was determined to find or produce, Dr. Weston does not rest, as most men do; on the contrary, he at once starts to get something still better; he is his own strongest and most determined competitor. The world was glad to get manganine, but he wanted something more; he wanted an alloy of practically no temperature coefficient, and having then gotten this, he wanted still more, a negative coefficient, something which there was no reason to think existed. As usual, he succeeded in producing it, but still was not satisfied until he had found several of them. The vastness of this metallurgical research will appeal to one when it is considered that there are quite a number of available metals, and that the various possible combinations of these in groups of two, three, four and more in different proportions, is practically infinite.

Nor did it satisfy him to find an alloy that had this desired quality, as it would be useless if it could not be drawn into a wire. Many of these alloys were stubborn and various thermal and mechanical operations had to be found before these otherwise desirable alloys could be made to yield to the wire drawing process. The thermo-electric properties when in contact with other metals also were an important factor and added to the complications.

The best standard cell known in those early days, for serving as a concrete voltage standard, was not considered by him to be up to his standard of ideals, and indeed it was a troublesome apparatus to use; so he gave himself the task of producing a better one; one which was more easily reproducible and had a lower temperature coefficient; the fact that many others all over the world had tried it but were unsuccessful, rather encouraged than discouraged him. As in other problems which he undertook, he succeeded, and gave to the world something far better

than the best it had had, and the world recognized it by making it the international standard; even the Germans now call it the Weston standard cell, though for years they contested the priority of invention. Its predecessor, the Clark cell, is now fast finding its way to the shelves of the museums.

Not satisfied with this standard of reference in which the solution was saturated at all temperatures, he also produced a working cell, the so-called unsaturated one, which saves the user some correction calculations, as it has a still better temperature coefficient.

That his instruments were ranked by electrical engineers as of the highest standard is best shown by the fact that the highest claim that competitors could make was that their instruments were "as good as a Weston," whether true or not. It was the pride of laboratories to be equipped with Westons. Disputed measurements were settled by using Westons. When a particular measurement was difficult or troublesome to make, Weston was appealed to to make an instrument to do it easily. Even electrical capacities can now be measured with a portable, direct reading Weston dial instrument, and perhaps a like simple method of measuring inductances will come next. So great was the demand that his list now includes about 4500 different types and ranges of instruments.

Though the credit for developing the fundamental, typical Weston instrument was disputed for years, the patent courts have given sweeping decisions in his favor.

Dr. Hering then discussed at some length Weston's work on dynamo design, on illumination by the flaming arc and by electric incandescent lamps and concluded his address as follows:

Nothing was good enough for him if there was any possibility of improving it, and nothing seems to be too difficult for him to undertake. When the best manufacturers of this country or abroad, including the finest watch makers, found it too difficult to meet his exacting requirements for some of the parts of his instruments, he undertook the task himself. To beat the best gave him pleasure. When he wanted a wire drawn to half a mil in diameter he made it himself, as no manufacturer would undertake such a task. He wanted a screw thread of 500 to the inch, on a 10 mil rod; no one had come more than half way to this, but he accomplished it, originating the taps and dies himself. Not very long ago machine work to a thousandth of an inch was considered the highest class of work, but this was not good enough for Weston, who now works to the millionth, one thousand times finer.

A characteristic of his work is that he insists upon completely finishing a piece of work in the privacy of his laboratory, before it is brought before the public, which is in marked contrast with the more usual course of publicly proclaiming in the daily press the great things one intends to do, and which often never materialize. Instead of selling futures he sold finished products. His high ethical principles were shown when in the early days of incandescent lighting he insisted on the equity of rating the lamps by their mean spherical candle power, instead of deceiving the purchasers by measuring them in the direction of maximum light, as was not infrequently done by others.

Among his other early achievements may be mentioned the use of an arc furnace in 1875-6 for melting platinum and iridium, hence prior to Siemens, whose arc furnace is usually cited as the first. Dr. James Douglas, who was the first in this country to refine copper electrolytically on a large scale, credited his success to the advice and assistance of Weston in 1878, when very erroneous ideas about its practical impossibility were prevalent among others.

His personalitly only those of his personal friends who have had the good fortune to have been guests at his home and have been intimately associated with him, can truly appreciate. The same laudable extremes to which he aspires in perfecting his products, he shows in his kindness and loyalty to his friends and associates, as also in defending himself against his enemies. His high ethical principles have made for him both staunch friends and bitter enemies. To profit from losses to those who have shown confidence in his work is repulsive to him; what gives him pleasure is to please them.

On whatever balances a man's life work may be weighed, the scale of last resort for measuring it is the question, "In what way has the world benefited by his having lived in it?" The summary of his work, as given here to-night, will answer this.

The whole evening was very enjoyable, though the proceedings extended to a very late hour. The former recipients of the Perkin medal were Sir William Perkin, J. B. F. Herreshoff, Arno Behr, E. G. Acheson, C. M. Hall, H. Frasch, James Gayley and J. W. Hyatt.

Pyritic Smelting at Mount Lyell

At a recent dinner of the New York section of the Mining and Metallurgical Society of America, Mr. **Robert Sticht**, general manager for the Mount Lyell Mining & Railway Co., Queenstown, Tasmania, spoke informally of his experience in pyritic smelting in that country during the past 20 years. His remarks were discussed in an interesting manner by several members of the Society. Mr. Sticht said in part:

"As regards smelting, when I arrived at Mount Lyell the pyrite method was still a problem. I had enjoyed opportunity to carry it out in its purity, for short periods, whenever the ores were suitable, in Montana and Colorado, and had no fear, on an empirical basis, that it would not be possible to carry it on continuously where the ore was so favorable as at Lyell. But, for my own satisfaction in fully understanding what went on inside of a furnace, I was made general manager too soon. I then had to look after the pounds, shillings and pence, and investigations of metallurgy, as such, had to be postponed.

"Briefly, we started with three blast furnaces in 1896 and then installed converters. This plant was gradually enlarged to six blast furnaces. A second plant was built with five furnaces. When we abandoned hot blast, after six years' use, we pulled down the first plant and did all the work in the second. This plant received an extra furnace in the course of time, so that it has six, but we usually run only three furnaces. The most interesting development, perhaps, was the discarding of hot blast. I do not think I would now recommend it under any conditions.

High Ore Column and Blast Pressure

"Our furnace column reaches 18 ft. above tuyeres, and we use 64 oz. blast pressure. We base our work on the assumption that the inside of a furnace is occupied by a honeycombed mass of quartz, the passages of which are traversed by the blast and the molten sulphide, in opposite directions, the incandescent silica effecting simultaneous oxidation of the latter, by the oxygen of the blast, and the union of the FeO, thus formed, with the silica itself. This forms the slag, while the unoxidized portion of the sulphide makes the matte. Our matte runs from 45 to 50 per cent., rarely under 35 per cent., and sometimes as high as 60 to 65 per cent. (a 20:1 concentration). When the matte becomes too high, we reduce the siliceous ore; when too low, we increase the latter. The proportion of pyrites in the charge is constant; also the limestone. The only variables are siliceous ore and coke, but the latter is changed much less frequently than the former.

"As regards the percentage of coke used, I regret to say that the time when we got along with only 1½ per cent. (and sometimes as little as 1/10 per cent., with hot blast) is now merely historic. We are now under the necessity of smelting more of the siliceous ore, and, at the same time, the iron and sulphur in the pyritic ore have diminished, owing to the inclusion of a little galena and zinc-blende and a little more gangue. As a consequence, we now employ from 3½ to 5 per cent. coke, figured on the materials charged (except coke). The coke is our own make, but high in ash, and wet from the rainfall, which is 110 in. annually. Our slags are also more siliceous than they used to be, averaging 35 to 37 per cent. SiO_2 as against 30 to 32 per cent. in the past. The campaigns used to be three months or less; now they are a good deal longer, easily six months, the stoppages being caused by leaky jackets or the forehearth.

"Concerning shape of bosh, I am unable to see that it makes any difference. The furnace creates its own

internal lines, which may be entirely different from those of the designer. One can alter the position of the smelting zone, i. e., the focus, by changing the blast. The focus can be driven up by increased blast, in fact it may be driven clear to the top of the column.

"You might think our works old-fashioned. We have kept fully in touch with all modern improvements and tendencies in the United States, but have not found that we could advantageously make use of the most striking ones. This is true as well of economic as of purely metallurgical points. Each furnace is run individually as regards momentary composition of charge, and the principal factor in their operation is the feeding. We have to be very particular about this, and cannot resort to mechanical appliances intended to serve unchanging average conditions of feed, because our process is so sensitive to variations in the relative proportions of silica, sulphide, and air, and to the physical way in which these three come together. You cannot run a number of pyritic furnaces all in the same manner and obtain our present grades of matte with satisfactory constancy. You would have to reduce the grade to, say 20 per cent., and be satisfied to re-treat this."

Mr. D. H. Browne called attention to the fact that the practice outlined by Mr. Sticht was not applicable to all ores which contain sufficient iron and sulphur to smelt them. Sudbury ores, for example, containing 35 per cent. iron and 20 per cent. sulphur, are theoretically amenable to pyritic treatment, but many attempts had been made without success.

Experience at Tennessee Copper Company

Mr. J. Parke Channing said: "About 15 years ago, when I was starting the operations of the Tennessee Copper Co., I heard of what Mr. Sticht was doing at Mount Lyell, in Tasmania, and Mr. Frank Klepetko kindly laid my problem before Mr. Sticht. He advised me that I had better not begin with pyritic smelting in Tennessee, but stick to heap roasting. We spent $70,000 putting in roast yards, then smelted the ore with 13 per cent. coke, making a 40 per cent. matte in the first operation, which was then converted. We made money, and everyone was satisfied. I fear that if we had started on pyritic smelting I might have made a failure of it.

"Shortly after this, Mr. Freeland, manager of the Ducktown Sulphur, Copper & Iron Co., whose property adjoined that of the Tennessee Copper Co., began pyritic smelting. At first his slags were too siliceous, and to correct them he tried adding iron ore. This only made matters worse; and eventually, after pounding away at it and trying all the various combinations, he found that what was necessary was to cut down the coke and add silica. To him is due the credit for the pioneer work in pyritic smelting in the Ducktown district.

"Having the benefit of his experience, I took one of our 56x180-in. furnaces, ran the ordinary roasted-ore charge down low, filled it up with the pyritic charge, with a minimum amount of coke, and the furnace ran perfectly. We found, however, that it did not make much better than 10 per cent matte, which was then concentrated in a second furnace and bessemerized. We were soon able to clean up the roast yards and operate entirely by the pyritic method. Incidentally, we noted an increased extraction, as apparently some inexplicable loss ocurred in the roast yards, which we were never able to trace. We were never able to reduce the coke so far as Mr. Sticht did, nor were we able continuously to get so high-grade matte as he. As the furnaces are now operated, the question of matte-fall is of secondary importance, the most important object being to produce a gas which can be used in the acid chambers for the production of sulphuric acid.

"The present aim is to yield a gas which will run about 6 per cent SO_2 and 9 per cent free oxygen, so that there may be enough oxygen to convert the SO_2 to SO_3 in the chambers. If the SO_2 is high, and the oxygen low, it will not do to add atmospheric air, because of the large amount of nitrogen thereby introduced, which dilutes the SO_2 below working requirements. The best way is to keep the coke down to a small amount so that too much of the free oxygen will not be consumed in burning this carbon.

"For many years I had maintained to Mr. Browne that there was no reason why he should not smelt the Sudbury ores pyritically. He haunted the works of the Tennessee Copper Co. for over a year, trying to learn how to do it. About two years ago he engaged Mr. George A. Guess, who had been in charge of the Tennessee smelter, to try the experiment at Copper Cliff. Mr. Guess was given a furnace and blowing engine, and any kind of ore and flux that he wanted. After about three months I received two letters in the same mail; one from Mr. Browne saying that Mr. Guess had given it up, and the other from Mr. Guess himself saying that he could not smelt the ores pyritically and did not know why.

"I have grave doubts whether nickel-copper ores can be smelted pyritically. Possibly there is some peculiar characteristic of the nickel sulphide which prevents the pyritic action from taking place. In addition, a large amount of the silica in the Sudbury ore is combined as a bisilicate, and the conditions in the furnace are not suitable for breaking up this combination. There is just a possibility that in a very high furnace the desired result might be obtained, though I am of the opinion that Mr. Browne will have to continue with his roast heaps, for the present at least. There is a possibility that in the Knudsen furnace the problem may be solved. There, none of the material can get away, and possibly the complicated reactions may take place."

Action of Pyrite and Pyrrhotite

Mr. Sticht was asked whether the difference in the action of the Australian and Sudbury ores might not be due to the fact that the former was a pyrite and the latter a pyrrhotite, the extra atom of sulphur in the former exercising a favorable influence on pyritic treatment. In reply, Mr. Sticht said that he believed there was a strong misconception regarding the utility of the extra atom of sulphur in pyrite as a source of heat in the pyritic process. This extra atom is not burned, but is distilled. The FeS_2 turns practically to pyrrhotite at once, and even to something like Fe_5S_6 or Fe_3S_4 in the lower part of the furnace, and it is this particular sulphide which supplies the heat. In many ways, I think, a pyrrhotite ore is probably easier to smelt than a pyrite ore, but I may repeat that the most essential condition for the process is to have *free* SiO_2. What experience I had with pyrrhotite ores in Colorado made me feel that they were easier to treat than pure pyrites. In addition to keeping the throat more free, they seem to run hotter. But it was necessary not to be afraid to reduce coke, i. e., to a minimum which would ordinarily seem dangerous.

"One ought to have several feet leeway in the height of his smelting column. In reconstructing the Mount Lyell works, I raised the charge floor eight feet above the former one. A separate blower for each furnace is desirable if one can afford it, but that is only a minor point when there are not too many furnaces. When formerly using hot blast, the stoves standing between

blowers and furnaces, it complicated matters to have a blower for each furnace, and we did not do that at Mount Lyell. Our practice now is to supply about 20,000 cu. ft. of cold, free air per minute to each furnace. The 64 oz. pressure is only an incidental feature of the blast, and is due merely to the resistance encountered in forcing a given volume of air through a certain size of tuyere in a given time. Roughly speaking, it is volume rather than pressure that counts.

No Oxygen in Furnace Gases.

"Regarding the composition of our furnace gases, since the figures were first published, we have occasionally repeated the analyses, and still find practically no oxygen in the gases leaving the furnace, nor at a depth of 7½ ft. below top of the column. The determinations were last made a few months ago, with a water-cooled apparatus."

"The furnaces at Mount Lyell appear to be running with hot tops. This is due to the large amount of sulphur distilling off, which burns as it comes in contact with oxygen of the air above the charge. It is possible to run the furnace on matte and pyrrhotite with a satisfactorily cold top. On pyrites, however, this is impracticable, for this low temperature can be achieved only by operating in a manner which leads to rapid formation of crusts around the throat. We run, therefore, so as to avoid crusts, and thus appear to have a fiery throat. One must, however, not contemplate the combustion of the sublimated elemental sulphur, but judge throat conditions rather by the phenomena at the top of column. The top of the furnace is really not hot, for the pieces of charge glow slightly only around the walls, and are black and cold over the full inner area of the top. Between these cold pieces a whitish flame is visible, which changes into a heavy cloud of sulphur vapor a foot or two above the top of charge; this then ignites and forms the usual dense white smoke characteristic of the work. The furnace acts as its own crusher; all materials are charged in as massive lumps as the men at the mines and quarries can readily handle. Possibly, if we crushed them first, they would so decrepitate in the furnace that the latter would choke tight, and we could not practice pyritic smelting."

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Improved Cam for Stamp Mills.—In the December *Bulletin* of the A. I. M. E., Mr. Arthur B. Foote describes an improved form of cam which he has used at the North Star mill in California.

"The cam at present in use lifts the tappets with an involute form of curve, to which the surface of the tappet is always tangent. Moreover, the line of contact between tappet and cam, if produced, would pass through the center of the stamp. While this is a desirable feature, the inventor had believed that it would be more desirable if the cam were to pick up the stamp without shock, and gradually increase the upward velocity throughout its movement. The involute cam attempts to impart instantly a high upward velocity to the stamp, starting it from a state of rest, and the result is a destructive blow, a good deal of noise, and much wear and vibration.

"The new form is one which is designed to lift the stamp with a motion similar to that of the piston of an engine between the end and middle of its stroke; in other words, harmonic motion, from the point of zero to maximum velocity. The curve will give this ideal motion only when the stamp is set for the exact drop for which the cam was designed, but the improved cam will not be as bad as the involute until the drop is reduced one-half. In other words, if a cam is designed for a 6-in. drop, it will be some improvement over the usual form of cam until the drop is only 3 inches.

"Any cam, of course, must lift its stamp in the same number of degrees of revolution, and therefore this new form, starting the stamp slowly, must end up by going faster, the average speed being the same. With this design, the surface of the tappet is not tangent to the surface of the cam throughout the lift. The possible consequences of this were studied with a full-sized model, and did not seem serious, since the engagement between the surfaces was an easy sliding motion instead of a blow. If the drop is shortened, the blow becomes more and more pronounced, but the surfaces also become more and more nearly tangent.

"Five cams of this design have been running in one of the mills of the North Star Mines Company for over a

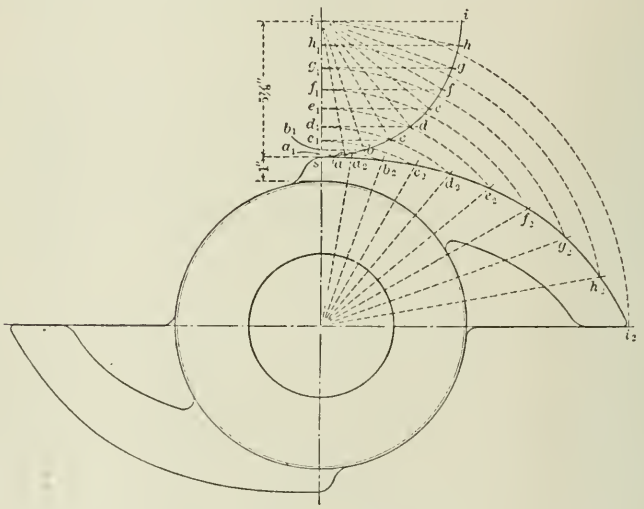

FIG. 1—IMPROVED CAM

month, fulfilling every expectation. Holding the hand on the tappet it is impossible to feel the cam strike it, although the mill is running 107 drops per minute.

"The accompanying drawing, Fig. 1, shows the method of laying off the curve of the cam, which will give approxiately harmonic motion to the stamp. The spaces sa_1, a_1b_1, b_1c_1, etc., represent the distances traveled by the cam in equal intervals of time."

Acid Treatment of Gold Precipitate.—Some practical notes on this subject are offered by Mr. H. A. White in the September, 1914, *Journal* of the Chem. Met. & Min. Soc. of S. Africa. The use of sodium bisulphate is becoming general in place of commercial sulphuric acid. This material is obtained as a by-product from dynamite factories, and contains from 28 per cent to 40 per cent sulphuric acid. Its use shows a saving over commercial acid.

"Where white precipitate is present in the boxes in considerable quantity, special precautions are advisable in the acid treatment. These include (a) emulsification of the white product taken from the filter press and the avoidance of the formation of greasy lumps which are very slowly acted upon by the acid. (b) Owing to the fact that the action of sulphuric acid is somewhat slow (especially in the presence of ferrocyanides) it is advisable to allow at least twelve hours' contact with hot acid in excess and to reserve some of the coarser zinc shavings, to be dissolved, for subsequent neutralization of the remaining acid. A considerable improvement in the value of the calcined slime is easily effected in this way."

The corrosion of the clay liners used in crucibles is observed to increase rapidly in the vicinity of cracks. In order to avoid the formation of these cracks it is essential that the liner should be evenly supported and heated. To attain this object it is well to fill the space between the liner and pot with powdered graphite, using crushed crucibles for this purpose. Liners supported in this manner will give up to 50 per cent more fusion than usually obtained.

"On some mines it is not found necessary to add any flux or oxidizer whatever to the well-calcined gold slime as it is self-fluxing and contains sufficient ferric oxide to keep the value of the bullion produced well above the level of the usual battery bars. The slag thus produced is fairly low in gold, but owing to unavoidable variations in the composition of the calcined slime, even on the same mine, trouble may be caused by insufficient fluidity of the slag or by undue corrosion of the liner.

"A method allowing a little more elasticity in conditions is to fill the liner within ½ in. with the gold slime and to pour on this, as a protective cover, a mixture of 1½ parts of fine sand and 1 part (by weight) of calcined borax. This may amount to 15 per cent or 20 per cent by weight of the calcined gold slime, and gives a fluid non-corrosive slag at a reasonable heat. I would suggest that preliminary experiments in this direction be made with two of the pots in a "pour," as any trouble can easily be rectified (by adding borax or otherwise) in the next melt, and the conditions are strictly comparable.

"It is clear from comparative experiments made with slime ranging in value from 10 per cent to 35 per cent of bullion that, as Mr. Dowling has pointed out (*Rand Metallurgical Practice,* Vol. I, p. 271, and *Chemical, Metallurgical and Mining Society's Journal,* Vol. VII, p. 212, January, 1907), the intimate mixture of flux and slime is not necessary, and this practice, which is conducive to loss of valuable dust, should by now be completely obsolete.

"By the above methods the value of the gold slag produced (after panning) may be reduced below 10 oz. per ton, and as the quantity is smaller the total value of such by-products as pots, liners, and slag should not exceed ½ per cent of the cyanide gold produced, and, in fact, in some cases is below ¼ per cent, while the buttons of gold from each pot have averaged over 100 oz. for some clean-ups. In this manner also a considerable saving in cost is shown."

Determining Dissolved Gold in Slime Residue.—Since vacuum filtration of slime became common practice, it has become increasingly necessary to know definitely the gold content of slime residue in order to regulate the dissolving and washing periods and secure the highest economic extraction. In a paper published in the monthly *Journal* of the Chamber of Mines of Western Australia Mr. L. R. BENJAMIN discusses the methods for determining the proportions of soluble and insoluble gold in filter residue, and points out possible errors in the work.

One method is to filter and assay the solution in the residue, and calculate the equivalent of dissolved gold from the percentage of solution to dry slime. The value thus obtained is then deducted from assay value of dried residue, giving the undissolved equivalent. Another method is to assay the dried residue for total gold; assay the water-washed residue for dissolved gold and get the undissolved equivalent by difference.

The author discusses the possibility of gold losses by either of these methods and finds two periods in the operation when high temperatures may cause loss of gold and affect the accuracy of the work. The first period is in the drying of the sample over a fast fire, when he finds that capillary attraction may cause a segregation of gold into a scale adhering to the pan. The second is during the assay fusion.

He found air-drying to yield higher results than fire-drying, but requiring a longer time for the work. In order to minimize the losses in rapid drying he suggests precipitating the dissolved gold prior to drying, and finds that the use of a 5 per cent cuprous chloride solution gives excellent results. As for fusion losses during assaying, he comes to the conclusion that they are "anything but a bogey," and always occur, varying directly with the amount of gold remaining in the combined state after drying, and due probably to volatilization.

Copper Smelting.

Coal-Dust Fired Reverberatory Furnaces.—In the January *Bulletin* of the American Institute of Mining Engineers there are two papers on the development and use of coal-dust firing for reverberatory copper smelting. The first, by Mr. D. H. BROWNE, reviews the history of the method and its adoption at the works of the Canadian Copper Company; the second. by Mr. L. V. BENDER, gives results obtained by the Anaconda Copper Company.

The use of reverberatory furnaces at the Canadian Copper Company's works was made necessary by increasing quantities of flue dust and fine green ore. When the practice was first considered, coal-dust firing was investigated and considered feasible. S. S. Sorensen had been the pioneer investigator in this line of work at the Highland Boy smelter in Utah, and had been followed by Charles Shelby at Cananea. Both had experienced trouble due to accumulations of ash as a blanket on the molten charge and in the throat of the furnace, but the trials indicated possible improvement in reverberatory smelting, particularly as regards fuel ratio. It was finally adopted at Copper Cliff, however, designing furnaces especially to meet the requirements by eliminating right-angled bends in the flues and placing the skimming door at the side instead of the end. The waste-heat boiler was made a secondary consideration. The first smelting showed no difficulty with the fuel, and as improvements were gradually made the smelting became more efficient. In the first three months of 1914 the fuel ratio was 5, 5.65 and 6.77, respectively. The method of feeding has been changed. At first it was done through hoppers near the fire end, but is now done almost entirely through pipes in the side walls. Coal dust is introduced through five pipes 5 in. in diameter. It is first dried and then ground so that about 95 per cent passes a 100-mesh and 80 per cent passes a 200-mesh screen. The great advantage found in this method of firing is the absence of breaks in the temperature curve due to grating or cleaning the hearth, and as a consequence a greatly increased tonnage and fuel ratio.

At Anaconda coal-dust firing was tried in June, 1914, in a furnace 124 ft. by 21 ft. The method of charging was similar to that used at Copper Cliff. From the experience gained in this work, Mr. Bender lays down the following requisites for successful use of coal dust: (1) The coal should be dried before pulverizing, containing not more than 1 per cent moisture; (2) fine pulverization affords increased area and higher thermal efficiency, 95 per cent should pass a 100-mesh screen and 85 per cent a 200-mesh; (3) the quantities of coal and air delivered to the furnace should be carefully controlled in order to secure complete combustion; (4) the coal should contain enough volatile combustible matter to give the required combustion, a standard for cement work is 30 per cent; (5) the furnace should be properly designed and equipped, and (6) provision must

be made for taking care of the ash. Based on past experience, some changes will be made in the new equipment for coal-dust reverberatory firing at Anaconda. The furnaces will be 144 ft. by 25 ft., with a flue area of 48 sq. ft. Matte will tapped at the front. The skimming plate will be 12 in. higher than in other furnaces, the top of the plate being 24 in. above the tap hole. Recent records for a week at Anaconda indicate the efficiency of coal-dust firing; the average tonnage per day was 542.7, with a fuel ratio of 7.5.

Concentration.

Flow of Sand and Water Through Spigots.—It is common practice in ore-dressing operations to pass pulps of sand and water through spigots, as in jig hutches, classifier pockets, etc. "With a given quantity of solids per unit time, of a given specific gravity, to be discharged with water under a given head, and with a given rato of water to solid, what must be the size of the spigot opening?" Such is the nature of a problem investigated by Prof. R. H. Richards, of Boston, Mass., and Mr. Boyd Dudley, Jr., of State College, Pa. Their results are published in the January *Bulletin* of the A. I. M. E. If a spigot is to be opened continuously, there are, aside from its form, three factors governing the rate at which it will discharge a given mixture, viz., the head of water above the spigot, the area of the spigot opening and the viscosity of the material discharged. By the term viscosity as used here is meant the ratio of the volume of pure water that will flow through a given orifice under a given head in a given time to the volume of the material under consideration that will flow through the same orifice under the same conditions.

The head of water above a spigot is usually fixed; so with the head known, in order to determine the size of the spigot required, it is necessary to know the viscosity of the desired mixture, and the coefficient of discharge of the form of spigot employed when pure water is discharged. From these data the area of the spigot can be calculated from the equation

$$a = \frac{fq}{c\sqrt{2gh}}$$

in which a is the area of the spigot opening, f being the viscosity of the mixture, q the rate of discharge by volume, c the coefficient of discharge, g the acceleration due to gravity and h the head of water above the spigot. The coefficient of discharge is the ratio of the actual rate of discharge of pure water to the theoretical rate as calculated from the effective head above the spigot. The value c for forms usually found in classifier spigots under heads of from 1 to 3 ft. is between 0.87 and 0.91, the higher values for lower heads.

The authors studied the relation between the composition and viscosity of sand-water mixtures. The sp. gr. of the sand was 2.72. Experimental results are given in the table.

Relation of Composition to Viscosity of Mixtures of Sand and Water

Kilos sand and water	Kilos sand	Kilos and litres water	Litres sand	Litres sand and water	Per cent sand, vol.	Per cent sand, weight	Viscosity mixture
9.20	0.00	9.20	0.000	9.20	0.00	0.00	1.00
9.30	0.45	8.85	0.165	9.02	1.83	4.84	1.02
9.35	1.10	8.25	0.405	8.66	4.68	11.8	1.06
9.35	1.40	7.95	0.515	8.47	6.08	15.0	1.09
9.40	1.90	7.50	0.699	8.20	8.53	20.2	1.12
9.40	1.95	7.45	0.717	8.17	8.78	20.8	1.13
9.55	2.20	7.35	0.809	8.16	9.92	22.0	1.13
9.20	2.25	6.95	0.827	7.78	10.6	24.4	1.18
9.05	2.50	6.55	0.920	7.47	12.3	27.6	1.23

It was found by these tests that when the amount of the sand in the mixture exceeded 30 per cent by weight, the spigot would produce a very thick discharge for a short time, but that continuous operation under these conditions was not certain, and clogging would result.

A concrete example illustrating these data is given. It is desired to discharge from the pocket of a classifier 40 tons of sand per 24 hours, together with water in the ratio of 1 sand to 3 water, by weight. The head of water above the spigot is 3 ft. The mean sp. gr. of the sand is 2.81. What must be the diameter of the spigot opening? The area of the opening can be calculated from the formula given.

Taking up the terms on the right hand of the equation is order, f, the viscosity, may be estimated as follows: The weight-ratio of water to sand in the mixture to be discharged is 3 to 1. Considering 100 g. of the mixture, the weight of water is 75 g.; its volume is 75 cc. The volume of the sand is 25 g. $\div$ 2.81 (the density of the sand) = 8.9 cc. The total volume of 100 g. of the mixture is 75 + 8.9 = 83.9 cc. Hence, the percentage of sand by volume in the mixture is 8.9 $\div$ 83.9 = 10.6. From the table the viscosity of a mixture containing 10.6 per cent of sand by volume is 1.17. Therefore $f = 1.17$.

The quantity of sand discharged per 24 hr. is 40 tons. One ton per 24 hr. is 0.631 kg. per minute. Forty tons per 24 hr. is $40 \times 0.631 = 25.2$ kg. per minute. The volume of sand per minute is 25.2 $\div$ 2.81 (the density) = 8.98 liters. The quantity of water per minute is three times that of the sand, $25.2 \times 3 = 75.6$ kg. = 75.6 liters. The total volume of sand and water per minute is 8.98 (sand) plus 76.5 (water) = 85.5 liters. The total volume per second is 85.5 $\div$ 60 = 1.43 liters = 1,430 cc.

Since the spigot is to consist of a short tube with a cone mouth on the influx end, the coefficient of discharge, c, may be assumed as 0.88.

In metric units $g = 980$ cm. per sec.^{2}; and the head, h (3 ft.), is 914 cm.

Substituting these values in the above equation gives, for the area of the spigot opening.

$$a = \frac{1.17 \times 1430}{0.88\sqrt{2 \times 980 \times 914}} = 1.42 \text{ sq. cm.}$$

The diameter may be obtained from the relation,

$$d = 2\sqrt{\frac{a}{\pi}} = 1.35 \text{ cm.} = 0.53 \text{ in.}$$

Recent Chemical and Metallurgical Patents

Iron and Steel.

Briquetting Fine Ore.—According to the specifications of a patent of Wilhelm Schumacher, of Osnabrück, Germany, the compression of finely divided iron ore, in which the iron is in a low state of oxidation, together with a catalytic agent such as calcium chloride, effects the conversion of the iron compound into a higher state of oxidation, and produces briquets suitable for use in the blast furnace. The inventor has observed that when flue dust, containing the lower order of iron oxides, is briquetted with a catalytic agent, sound briquets are produced; and further the iron becomes oxidized. In the light of these facts, he proposes to briquet fine iron ores by first reducing them with coal dust, then mixing with lime if necessary, and briquetting. The mixture of ore and coal is heated to 500° or 600°C.; or to a lower temperature, say 400° to 500°C., at which temperature it may be treated with gases containing carbon monoxide. In either case reduction occurs, and the product is ready for mixing and briquetting. If the last process is performed at great pressure, the admixture of a catalytic agent may be entirely unnecessary. (1,121,048, Dec. 15, 1914.)

Furnace for Heating Billets.—A special type of furnace for heating billets or ingots preparatory to rolling, is patented by Mr. JEROME R. GEORGE, of Worcester, Mass. The furnace consists of a long channel, at one end of which the billets are introduced sideways and caused to travel to the opposite end, where they are removed. Heating gases enter the furnace at the discharge end, and are directed under and around the billets in a manner that gives high fuel efficiency. Near the discharge end of the furnace, the floor is inclined downwardly to facilitate the collection and removal of cinder, slag and molten metal that drips from the billets as they become highly heated. (1,121,621, Dec. 22, 1914.)

Liquid Fuel for Furnaces.—A new process of generating heat, particularly applicable to the melting of metals and smelting of ores, is patented by Mr. BRADLEY STOUGHTON, of New York City. The essential features are the use of fluid fuel to supply all or practically all the heat needed, and the use of a minimum quantity of solid fuel, the function of which is to be maintained incandescent for the purpose of igniting and insuring complete combustion of the fluid fuel without waste. Sufficient air is admitted to insure complete combustion of the fluid fuel and to keep the solid fuel incandescent, it being an object to consume the latter as slowly as possible. The process may be applied to shaft furnaces and some forms of reverberatory furnaces. A heated blast of air may be used, and steam for atomizing the oil. The process may be applied by placing at the bottom of a furnace a thin bed of coke, on this a layer of ore or metal, then a layer of coke, and so on. The coke bed is then ignited and the oil injected into the incandescent mass with sufficient air to insure complete combustion of the oil and incandescence of the coke. (1,117,274, Nov. 17, 1914.)

Making Manganese Steel from Scrap.—In a patent recently granted to Dr. HENRY M. HOWE, of Bedford Station, N. Y., he discloses a method of remanufacturing manganese steel scraps into manganese steel articles in which the necessary critical relation between the proportions of carbon, manganese and iron are maintained. In brief the process consists first in melting and mixing scrap and manganiferous material, such as commercial ferromanganese, in suitable proportions to produce the critical ratio between carbon and manganese in the mixture, with a suitable allowance for the changes in the proportions of these elements which will take place from the reactions incident to melting. In other words, the proportions must compensate for the loss of manganese by oxidation and the gain in carbon by absorption from the fuel. Having established this ratio, the mixture is diluted with carbon-free iron, such as blown Bessemer metal, until the amounts of carbon and manganese bear to the whole the desired percentage relation. The final adjustment of proportions may be made in an open-hearth furnace. (1,117,384, Nov. 17, 1914.)

Removing Rings from Nodulizing Kilns.—In order to remove rings of slagged material accumulating in rotary kilns used for nodulizing iron ores, Mr. FRANCIS B. DUTTON, of Lebanon, Pa., proposes to introduce water under pressure against the surface of the adherent ring. According to the patent specifications this is accomplished by arranging a series of water pipes along the length of the kiln, said pipes being connected with a header and extending through the kiln wall. Water introduced through these pipes under pressure would come in contact with the surface of the hot slagged mass, and by the sudden generation of steam, as well as by the force of the water, the accumulation would be dislodged. The operation is performed in a short space of time, does not allow the kiln to cool to a substantial degree, and eliminates the application of manual labor to the removal of the rings. (1,117,814, Nov. 17, 1914.)

Gold and Silver.

Filtering Apparatus.—Two types of filtering apparatus for slime have been patented by Mr. O. J. SALISBURY, of Salt Lake City, Utah. The first is a filter press consisting of a casing of circular cross-section, and containing the filter leaves or elements suitably connected with a source of vacuum. In order to facilitate the inspection of the press and the discharge of the cake formed on the leaves, the casing or shell is formed of similar sections hinged along an upper median line, and capable of opening and closing in unison. When in the closed position the sections are locked to make a liquid-tight joint. In operation the casing is charged with slime, under pressure, and the filtered liquid passes through the leaves and suitable connections to an outside receiver. The cakes thus formed on the filters are discharged by opening the hinged sections of the casing. (1,120,628, Dec. 8, 1914.)

The second type of filter is cubical in form, the casing consisting of two sides and ends rigidly connected, while two of the sides are designed for removal to form a clear passageway through the casing for the unabstructed discharge of the filter cakes. The casing contains filter leaves or elements suitably connected through a header with an outside receiver. The removable sides are rotatable about the casing, and the entire apparatus may be rotated to bring it into a position for discharge. In both types of apparatus the cakes are formed and washed by hydraulic pressure, and discharged by reverse pressure of a fluid in the filter leaves. (1,120,629, Dec. 8, 1914.)

Copper and Cobalt.

Copper Leaching and Electrolysis.—A hydrometallurgical process for copper sulphide ores patented by Mr. N. V. HYBINETTE, of Christiania, Norway, consists in roasting the ore to a point beyond the formation of Cu_2S but not to complete oxidation, leaching with sulphuric acid and precipitating by electrolysis. The ferric iron salts in the solution are used to dissolve the sulphide of copper remaining in the ore due to incomplete roasting. The inventor states that the disturbing influence of ferric salts on the deposition of copper does not occur before the amount is above 10 gr. ferric iron per litre, and the process does not become practically impossible before the amount rises above 15 gr. per litre. The rapidity of oxidation of the iron salts depends on the amount of ferrous iron in solution, proceeding with almost theoretically rapidity as long as there is present not more than 30 gr. ferrous iron, but ceasing as long as there is only 15 gr. ferrous iron. Therefore as long as there is not much more than the 30 gr. per litre present, the oxidation of iron above 15 gr. per litre as ferric sulphate goes forward very slowly, and the dissolving of the cathodes does not present unsurmountable difficulties at that degree of concentration of ferric salts. At the same time he has found that most of the copper sulphide in the roasted ore is readily soluble in a solution containing 15 gr. iron as ferric sulphate, but insoluble if the concentration falls below 10 gr. per litre. Therefore, by holding the iron content at a concentration of about 30 gr. per litre, the process may be successfully conducted.

The ore is roasted so that about 25 per cent of the copper is present as sulphide, insoluble in 5 per cent sulphuric acid solution. A solution containing about 30 gr. iron and 20 gr. copper as sulphates, and 60 gr.

free sulphuric acid per litre, is circulated between the electrolytic cells and the leaching vats. The solution entering the cells is regulated to contain about 30 gr. per litre, and leaves with about 20 gr. The solution entering the cells contains about ferric iron in quantity from 2 to 5 gr. per litre, and about 15 gr. on leaving. Thus about 10 gr. copper is plated and about 10 gr. iron oxidized. The success of the process depends on roasting the ore to the correct point, and in maintaining the proper amount of iron in solution. The latter is regulated by periodically discarding some of the solution. (1,122,759, Dec. 29, 1914.)

Electrolytic Production of Wire.—An invention relating to the production of copper wire by electrodeposition and drawing, is patented by Mr. William E. Gibbs, of Plainfield, N. J. It has for its object the production of a wire of high electrical conductivity and of superior quality due to the exclusion of impurities occurring in the ordinary drawn wire. The wire is carried automatically through electrolytic vats containing an electrolyte of about 3.5 per cent copper and 10 per cent sulphuric acid at a temperature of about 140 deg. F. (1,120,191, Dec. 8, 1914.)

Reduction of Cobalt.—The reduction of cobalt and similar metals from combinations with arsenic, sulphur and similar metalloids may be accomplished according to a patented process of Dr. Colin G. Fink, of Schenectady, N. Y. He mixes the ore with a reaction mixture which, upon heating, yields a metal having a higher heat of combination with non-metallic elements than that of the metal which is desired to recover. Such a mixture is calcium carbide and calcium oxide, yielding calcium and carbon monoxide. The liberated calcium combines with the metalloid of the ore and liberates the metal. Thus, in the case of cobalt in smaltite

$$2CaO+CaC_2=3Ca+2CO$$
$$CoAs_2+3Ca=Ca_3As_2+Co$$

The process is conducted in a vacuum furnace at a temperature as high as 1500 deg. C. (1,119,588, Dec. 1, 1914.)

Lead and Zinc.

Bag House for Lead Smelter.—Mr. Willard E. Playter, of Collinsville, Ill., has patented apparatus for controlling bag-house operations, causing them to occur automatically in proper sequence. The apparatus is electrically operated and controls the supply of gas and means for shaking the bags. The essential features of the apparatus are a motor and a drum controller provided with contact members. As the drum revolves the contact members cooperate with brushes in circuit with solenoids controlling air valves. These valves operate the dampers that open or close the ports between the flue and the bag-house units, admitting or excluding gas from any unit. They also control the shaking means, which consists of an air chamber above each bag and a depending flexible tube or hose within each bag. When air is admitted to the chambers and passes through the tubes, it causes the latter to vibrate with considerable violence and shake the accumulated dust from the bags into the cellar beneath. The apparatus may be adjusted as regards time so that the different operations occur in proper sequence at stated intervals. (1,118,045, Nov. 24, 1914.)

Electric Zinc Furnace.—A zinc furnace of the resistance type has been patented by Mr. Otto E. Ruhoff, of Madison, Wis. The furnace has a number of charge openings distributed along its top, a set of electrodes at the top in contact with the charge and a corresponding set of electrodes at the bottom. The walls of the furnace are provided with a relatively large number of condensers so that condensation can be accomplished quickly. (1,121,874, Dec. 22, 1914.)

Recovery of Zinc from Waste Liquors.—The extraction of zinc from liquor containing ferrous iron, as in the case of liquors from which copper has been precipitated by means of iron, is patented by Dr. Wilhelm Buddeus, of Charlottenburg, Germany. Both the zinc and iron are precipitated by means of lime, filtered and dried. During the drying process the ferrous iron is oxidized to ferric oxide, and from the resulting product the zinc may be dissolved by means of acid. The quantity of acid used is regulated by the amount of zinc in the mass. The resulting leach liquor is separated and treated as desired to recover the zinc. (1,120,683, Dec. 15, 1914.)

Electrical Precipitation of Suspended Matter

The corona discharge is utilized to precipitate suspended matter from gas, according to specifications of a patent granted to Messrs. William W. Strong of Pittsburgh, and Arthur F. Nesbit, of Wilkinsburg, Pa. The patent is assigned to R. B. Mellon, of Pittsburgh. The effect of the introduction of a spark gap in series with the active or grounded electrode is to extend the luminous region about the active electrode, and this fact is used in connection with the separation of suspended matter from a gas. (1,120,561, Dec. 8, 1914.) Apparatus that will throw on the high tension electric current used for such separation, only when suspended matter of a certain density exists in the gas, is the subject of a separate patent granted to Mr. William W. Strong. (1,120,560, Dec. 8, 1914.)

Electric Treatment of Emulsions and Dusty Gases

Petroleum emulsions can be freed from water by treatment in an electric field in suitable apparatus. The potential between electrodes is maintained sufficiently high to positively cause a puncturing of the oil between the different particles of water, so that they coalesce in a practically continuous chain between the electrodes. When the current is interrupted, the chains coalesce into a globule of water which then drops out of the oil. The patented apparatus and method are illustrated in the specifications. (1,116,299, Nov. 3, 1914.)

The electric precipitation of dust or suspended particles in a gas is patented by Messrs. W. W. Strong, of Pittsburgh, and A. F. Nesbit, of Wilkinsburg, Pa. The patent is assigned to R. B. Mellon, of Pittsburgh. The electrode maintained at a high difference of potential. The grounded electrode is formed in the shape of cells through which the dust-laden gas is passed, and within which is placed the active electrode. The dust is precipitated onto the grounded electrodes or into deposition chambers. (1,119,469, Dec. 1, 1914.)

Metallurgical Furnace

A roasting furnace is patented by Mr. Utley Wedge, of Ardmore, Pa., being of the superposed-hearth type in which stationary hearths alternate with rotating hearths. The rotating hearths are attached to a central rotating shaft. Both the fixed and rotating hearths have depending rabbles attached, so that material fed onto any one of the rotating hearths will be moved outward and discharged over the edge of the hearth onto the fixed hearth below, when it will be moved inwardly to the central point of discharge onto the moving hearth below. (1,119,483, Dec. 1, 1914.)

The Foreign Trade Movement was the keynote of the convention held on January 21 and 22 by the National Foreign Trade Council at St. Louis. President Farrell of the Steel Corporation is the chairman of the Council. Upwards of 300 delegates were in attendance.

Notes on Chemistry and Metallurgy in Great Britain

(From our London Correspondent)

The War and Engineering Industries

Conditions have improved considerably during the last few weeks in the engineering trades generally. At Sheffield there has been a decided advance in almost all classes of work as well as the exceptional briskness due to increased output of war material; while important orders from the French Government are virtually secured. The demand for warlike stores maintains great activity in Birmingham works producing such material; but those not so employed are by no means so happily circumstanced. Very large orders for motor-bicycles have been placed, and over a thousand of these machines are being built for the Russian Government. In South Wales the iron and steel works are growing busier; and the output of railway rolling stock, galvanized sheets, nickel and copper has attained very large dimensions. In the northeastern district manufacturers continue to experience considerable difficulty in securing adequate labor to cope with the Admiralty and War Office orders.

Labor troubles have been threatening at Elswick, but so far the dissatisfaction of the men with certain new conditions has not led to any interruption of work, and the matter appears likely to be smoothed over. On the Clyde numerous contracts for cargo steamers have been placed, and the outlook is very satisfactory. Sir W. G. Armstrong, Whitworth & Co., of Newcastle, have secured the contract for three pairs of gates for the north basin and central dock entrances at West Hartlepool, the order for which material was originally given to a German firm at Oberhausen; and among other contracts transferred from German workshops is one for six locomotives for the Taff Vale Railway which has been placed with the North British Locomotive Company of Glasgow.

* * *

At a meeting of the Birmingham Chamber of Commerce on November 30, the chairman, Mr. Sambridge, said that most of the gloomy forebodings entertained at the beginning of the war had been entirely falsified, and, instead of industries being paralyzed, trade was in a very healthy state, and many firms were encountering great difficulties through shortage of labor. Of course, some trades had been rather badly hit, but even with these there was now an improvement. Closed markets must be replaced by others. There was a great improvement in the financial position with a gradual but steady re-establishment of credit, while exchanges were easier. War was necessarily wasteful, but they must not lose sight of the fact that a very large proportion of the sums of money which the country had to provide would be spent at home and would benefit our industrial population. The action of the Government with regard to aniline dyes might well be extended to other products with advantage to home manufactures.

The Prevention of Explosions in Mines

The Home Office committee on explosions in mines has issued its sixth and final report on the experiments which have been carried out during the last three years at Eskmeals. Three methods of preventing, or, at all events, greatly reducing the risk of explosions are recommended: (1) The maintenance throughout the roads of such a proportion of incombustible dust in a state of fine division as would make a mixture yielding on incineration at least 50 per cent of ash; (2) the maintenance of at least 30 per cent of water in a state of intimate mixture with the coal dust throughout the roads, and (3), a combination of methods (1) and (2), adding the water after the incombustible dust.

Charges of 24 ounces of blasting powder fixed from a cannon in the large gallery at Eskmeals had failed to cause ignition of a mixture of equal parts by weight of coal dust and incombustible dust when the gallery contained atmospheric air only, or when the air contained as much as 2.3 per cent of coal-gas; but when the air contained 2.5 per cent of coal-gas or sufficient firedamp (obtained from Cymmer Colliery, Glamorganshire) to yield 4.6 per cent of methane, the mixture of dusts was ignited, and flame traveled throughout the gallery. No ignition occurred when the air contained 4.5 per cent of methane. The lower limit explosive mixture of methane and air under ordinary conditions requires 5.6 per cent of methane. The efficacy of the incombustible dust appeared to depend more on the degree of fineness than on its composition, and unless the dust contains not much less than 50 per cent by weight of particles capable of passing through a 200 x 200 sieve more than one part of incombustible dust to one part of coal dust is required to prevent ignition. With reground Altofts shale and superfine dolomite dusts containing respectively 55 and 66 per cent of the stated degree of fineness one part to one part of coal dust was sufficient; with flue dust, 31 per cent 200 fine, and dolomite dust, 42 per cent 200 fine; 1½ part to 1 of coal dust was necessary, while three parts of sand, 4 per cent 200 fine, to one part of coal dust was found to be insufficient to prevent ignition.

With regard to watering, experiments conducted by the United States Geological Survey some years ago demonstrated that, in order to prevent propagation of flame, the coal dust must be admixed with about 30 per cent of water, and while this quantity does not produce a wet mixture with fine coal dust, 40 per cent of water produces a muddy mixture. Similar experiments have been repeated at Eskmeals, both with coal dust in its natural state and with mixtures of coal dust and incombustible dust, and the results confirm those arrived at in America. With mixtures of coal dust and incombustible dust the Eskmeals experiments went to show that the amount of water required to render the mixture non-inflammable varied inversely as the total ash of the mixture. The coal dust mixture containing 15 per cent of ash would require the addition of from 25 to 30 per cent of water to render it incapable of propagating flame, and each additional 10 per cent of ash in the mixture reduces the requisite quantity of water by about 5 per cent. The nature of the incombustible dust also has a decided effect. Shale dust absorbed moisture more readily than Fuller's earth and formed a binding material which had an agglomerating effect on the fine coal dust which remained caked after drying.

The committee arrived at the conclusion that a combination of "stone dusting" and watering is preferable to either method alone. The manner in which the water is applied to the coal dust has considerable influence on the quantity required. Mixtures prepared outside the gallery and then spread along it by the hand resisted ignition when 30 per cent of water was present; but the spraying of 30 per cent of water by means of jets or rose sprays on the dust strewn along the gallery would not be equally effective, because watering by such means only moistens part of the dust while most of it is swept from the ledges to the floor, forming pools of water and dry dust accumulation without admixture. But when atomizers, delivering the water as a fine mist, were used, it was established that coal dust moistened with an equal weight of water resisted propagation of flame for more than a short distance, even when the conditions of ignition were severe.

This report would be more satisfactory if it represented the unanimous opinion of all the members of the committee, but unfortunately two members, Professor Dixon and Mr. W. C. Blackett, who are not directly connected with the Home Office, have withheld their approval. Moreover, every practical man will recognize that there would be very great difficulty in uniformly maintaining the conditions recommended by the committee; and the protection afforded would not be continuously effectual.

Copper and Nickel

Application of Chloridizing-Roasting to Separation of Copper and Nickel.—The possibility of treating heavy sulphide ores, such as those of Sudbury, Ontario, containing much iron and small amounts of copper and nickel, by chloridizing and removing the copper, leaving an iron-nickel oxide product suitable for production of nickel-bearing iron by smelting in the blast furnace, has been investigated by Mr. Boyd Dudley, Jr., who presents some of his results in the December, 1914, *Bulletin* of the A. I. M. E.

The author first studied the reaction involving the production of chlorine from sodium chloride by the action upon it of sulphur trioxide and atmospheric oxygen. In the roasting furnace the sulhpur trioxide would be obtained from the decomposition of sulphates formed in roasting the ore, and the oxygen would be supplied from the air in contact with the roast. It appears from his experiments that the rate of reaction becomes appreciable at about 500 deg. C. and increases rapidly with rising temperature. The highest temperature attained was 769 deg. C. Another reaction studied was that involving the combination of sodium chloride, silica and oxygen, to form sodium silicate and chlorine. It was found that up to the temperature at which salt melts, 800 deg. C., salt was not decomposed to an appreciable degree.

Experiments were then performed on the chloridation of copper and nickel oxides, using mixtures of copper and nickel oxide with ferric oxide, silica, ferric sulphate and sodium chloride. With copper only it was shown that the completeness of chloridation increases with increasing temperature (500 deg. C. to 700 deg. C.) and increasing time (2 to 4 hours). Considerable copper was volatilized. With nickel only the volatilization was almost nothing, but the production of water-soluble nickel was small, being only 17.7 per cent at 550 deg. C. When both copper and nickel oxides were in the mixture, a maximum of 3.3 per cent of the nickel was converted into water-soluble and volatile compounds at 650 deg. C.

While these laboratory experiments do not prove the commercial feasibility of the proposed process, they suggest the possibility of effecting a separation and indicate the temperatures at which the roast should be conducted.

British Aniline Industry

In furtherance of the scheme for constituting a purely British undertaking for the purpose of manufacturing aniline dyes and allied products the government proposes to guarantee interest on a million and a half of debenture capital, subject to nomination of two members of the board by the government and to a veto which will insure exclusive and permanent British control. There is also a provision securing uniformity of prices to large and small consumers alike. To this outcome of the negotiations the energetic part played by Lord Moulton has contributed in no small degree.

Hydraulic Disruption in Mining

At a recent meeting of the Society of Engineers, Mr. James Tonge contributed a paper describing a "hydraulic mining cartridge," which, it is claimed, may be very advantageously substituted for blasting in mines of all descriptions, for excavations in rocks, breaking up concrete beds, and similar purposes. The instrument consists of a strong steel cylinder with lateral telescopic rams to give a long thrust. It is made in three sizes varying from 2½ to 4 inches in diameter, with eight rams in the smallest size, six in the intermediate, and five in the largest, and is worked at pressures of from three to five tons per square inch.

The general procedure in working wall coal is to drill a series of holes in the seam, from 6 ft. to 10 ft. apart and 3 ft. to 5 ft. deep, near and parallel to the root, and pump off the holes in succession from the free face of the seam. In headings the coal is undercut and sheared vertically in the middle, when one hole on each side of the shear, close to the fast side, will suffice. One man using one machine can pump 30 to 40 holes per 8-hour shift, and the machine will last, with repairs, from three to four years. A colliery in which over 1000 blasting charges were fired every week has adopted the hydraulic apparatus and entirely discarded explosives. In one 3-ft. seam with four machines in daily use, some 28,500 hydraulic thrusts were made in a year and gave an estimated output of 92,626 tons, about 3¼ tons for each thrust. In another case five machines are getting 450 tons per day with 75 per cent large coal and 25 per cent small as against 65 per cent large when explosives were used. Taking the price of large coal at 13s. and of small at 7s. the increase in value due to the five machines works out at £14 5s. per day, without counting the extra 6d. per ton the coal brought down with the machines commands on account of its superior hardness and freedom from dust.

The paper also gives particulars with regard to excavating rock and removing concrete beds which indicate that the hydraulic cartridge works quite as efficiently for these purposes as in coal mining.

Market Prices

Lead opened £18.10.0, was £18.15.0 on the 10th, and remained steady for the ensuing week, then rising to £19.10.0 on the 23d, £19.15.0 on the 24th, at which price it remained to close.

Hematite has been steady at 62/—.

Scotch Pig opened 55/4½ and rose from the 17th, reaching 56/10½ on the 23d and 57/4½ on the 25th.

Cleveland opened 49/— and was stronger after the 16th, rising fairly steadily from 49/4½ on that date to 51/6 on the 24th, but only 51/3 on the 25th. It improved toward the end of the month.

After the 16th the metal exchanged reopened for a short time each morning.

Copper at the end of October was about £55. In the earlier part of the month it ran easier, in anticipation of the settlement, being £50.10.0 on the 10th and about £52 on the 13th. By the 17th it had reached £53 and was £55.5.0 on the 23d, was rather easier on the 26th at £55 and closed (settlement price) £54.5.0.

Tin opened about £133 and was £139 on the 10th, re-

maining about this price to the 17th, when it was £138.10.0. By the 23d it was £139.15.0, £140 on the 24th, and £142 on the 25th. On the 26th it had reached £142.5.0 and closed £142.10.0 (settlement).

A New Continuous Filter

There has recently been installed at the Concentrating Mill of the Pennsylvania Steel Company at Lebanon, Pennsylvania, a continuous filter with several interesting and novel features which should insure for it wide application in many industrial operations. While rotary vacuum filters of various types have been on the market for years, there appears to have been little departure, aside from the mechanical design, in the filtering medium proper, and too little attention has apparently been given to the maintenance of the filter in the most efficient condition.

In principle, this new filter is virtually a wheel with shaft, hub, spokes and rim, rotating one-half submerged in the pulp to be filtered and operated by a vacuum. The hub carries a valve, the integral parts of which register with the port holes in the hub, said port holes communicating with the compartments formed by the radial spokes of the wheel.

The wheel is constructed entirely of cast iron and for convenience, the compartments are cast two to a segment, there being eight segments, or sixteen compartments, each being isolated from the other, communication being only through the port holes in the hub to the valve.

Between the radial spokes, so called, a web, which is cast in each segment, supports the filtering medium proper, this covering both faces of the wheel.

The segments are not truly symmetrical, but radiate from the hub at such an angle as to bring the peripheral end and the hub end to very nearly a horizontal position, three or four inches above a horizontal center line of the wheel.

This is done because the cake discharges at this point and because, by such an arrangement, the entire compartment is immersed in the pulp by the time the hub end is and no vacuum is thereby lost by having a bare plate exposed to the atmosphere. As the wheel rotates, the effect is that the rim end of the segment travels ahead of the hub end.

The wheel may also be built of other material than cast iron, should the occasion require.

Construction of this kind permits of a large filtering area in a comparatively small space, the total thickness of the complete wheel being but eight inches and with a wheel 10 feet in diameter, there is an available filtering area of 150 square feet. One or two wheels may be operated in the same tank, saving thereby considerable floor space and requiring a maximum head room of 11 feet.

The filtering medium proper is "filtros," a comparatively new porous, mineral medium which has been prepared in special segmental shapes for this device and which shapes are bolted on to the faces of the wheel through a center hole in each shape, the retaining washers being countersunk so that both faces present smooth, rigid, permanent and practically indestructible surfaces.

The seams between the segmental shapes, which are very narrow and hardly noticeable in operation, as well as the seams between the filtros and the cast iron portions, are filled with a suitable cement, which makes the confined areas proof against leaks and avoids some of the annoying features, so common to numerous filtering devices.

The advantages of such a porous medium over the usual canvas or other fibrous covers are obvious, as with ordinary care, it should last as long as the iron work itself. No frequent replacement or renewals with the time losses incident thereto, no muddy filtrate from a punctured canvas, no tears or breakage from excessive pressures as numerous tests have shown the material capable of sustaining pressures of 100 pounds per square inch, no taking down for scrubbing or cleaning, as filtros may be scrubbed with wire brushes or given an acid bath, if necessary, in place; the cast iron, of course, preventing the excessive use of strong mineral acids.

Furthermore, filtros can be supplied in such grades of porosity as will make the device applicable to the finest slimes or the coarser concentrates or fibrous pulp, giving in all cases where the pulp permits of proper treatment, an absolutely clear filtrate which requires no further clarification. With the appropriate grade of filtros selected, there is but little tendency for clogging of the porous medium and as noted later, the plates covering each compartment are subjected to a back pressure at a certain point in each revolution of the wheel.

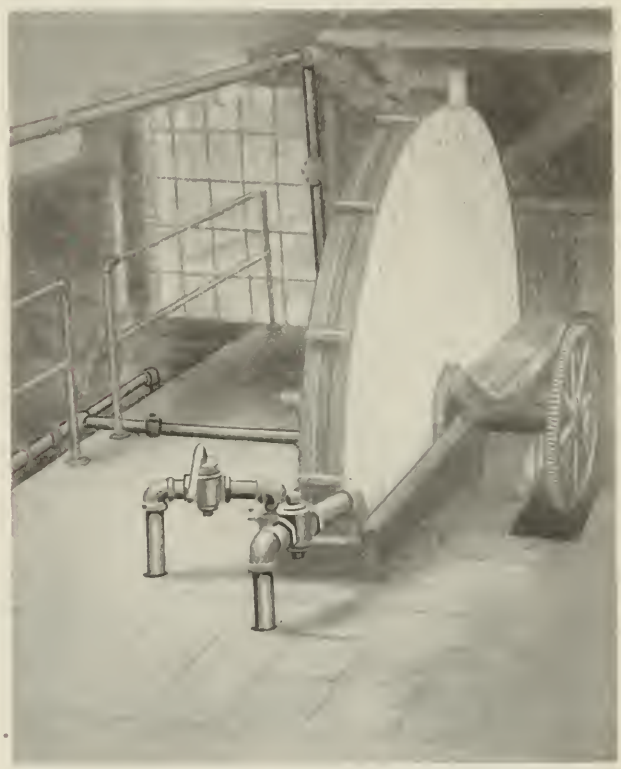

FIG. 1—CONTINUOUS FILTER

For a general cleaning up, a by-pass from the compressed air to the vacuum line permits the entire interior in the wheel and the filtros plates covering it to be thoroughly flushed with air or water. This can be accomplished in ten minutes' time by simply manipulating a few valves, and, depending upon the nature of the pulp being filtered, cleaning should be required only at infrequent intervals.

As stated, the wheel is vacuum operated, the full lower half only being constantly in the pulp. This is made possible by inserting packing collars in the walls of the tank, so that the hub and shaft are partly below the tank top, the said walls being carried to such a hight that there is at least one inch leeway when the wheel is just half submerged.

An over-flow is located at this point on one end of the tank, so that it is impossible to overflow the tank proper.

An outlet is also provided in the tank bottom for discharging the pulp remaining therein should a shut down be necessary, such amount always being small as but about two inches clearance is allowed all around for the wheel.

The wheel so nearly fills the tank that a comparatively small amount of pulp is in it at any one time and the tendency for the pulp to settle and retard the rotation of the wheel or to filter unevenly is thus avoided. Furthermore, the lugs on the rim of the wheel act as rakes for constantly stirring up the pulp and should the occasion require, as may be the case with a very heavy sediment, additional rakes extending both radially and lengthwise, can be attached to said lugs so that settlement of the pulp is impossible, as the sediment would be raked up for the full width of the tank sixteen times for each revolution of the wheel.

Additional agitating devices, which are required in many forms of continuous filters, are thus eliminated.

In the present illustration, the tank does not conform to the circumference of the wheel, though if desirable, it could be made semi-circular.

A door is also located on one side of the tank near the bottom, which is merely for use in emergencies, as when a tool or something of the kind may have been dropped in the tank.

The pulp is fed to the filter tank in the present in-

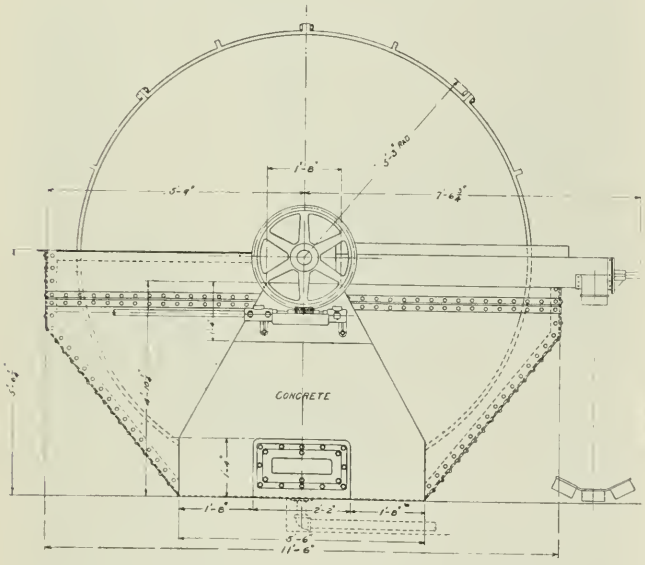

FIG. 2—SECTION OF CONTINUOUS FILTER

stance by two three-inch lines directly from the thickeners, though in some installations, an intermediate storage tank with constant level float valve may be desirable. The rate of filtration is so uniform, however, that no difficulty has been experienced in regulating the direct feed line.

The rate of revolution can be varied for most efficient results, these being dependent upon several factors. In general, it has been found that one revolution in three minutes is most desirable, this, with ordinary pulp, producing a cake of such thickness that it is easily discharged from the wheel and also lends itself to easy washing.

All else being equal, the faster the wheel revolution, the greater the tonnage capacity, though not necessarily the most effective results. For example, at the higher speeds, the cake contains more moisture and with the thinner pulps, the cake produced is not so easily handled.

The following brief table, showing some results on a lime sludge, will make these effects clear. The temperature of the pulp was in all cases, 50 F. (which is too low for best results, there being at least 50 per cent increased capacity at 100 F.), the proportion of solids was 36 per cent, liquid 64 per cent and the vacuum 22 inches.

One Revolution of Wheel In	Thickness of Cake	Moisture in Cake	Tons per Hour: Dry Matter	Tons per Hour: Wet Cake
4 min.	About 1″	37%	3.84	6.03
3 min.	About ¾″	39%	4.58	7.56
2 min.	About ½″	40%	5.03	8.44
1 min.	About ¼″	40.5%	5.48	9.28
0.5 min.	About ⅛″	41%	6.30	10.75

As a good illustration of the temperature effects, the following table applying to the same pulp may be cited, all at one revolution of the wheel in three minutes and at 22 inch vacuum.

Temperature, Deg. F.	Moisture in Cake	Tons per Hour: Dry Matter	Tons per Hour: Wet Cake
50	39%	4.58	7.56
61	39%	5.16	8.51
67	39%	6.05	9.99
81	39%	6.64	10.96

from which a marked increase in capacity is noted at the higher temperatures.

But to return to the operation of the wheel. As stated, each of the sixteen compartments communicates independently to the valve, the latter being made for either a right or left hand rotation and having on its outer face, near the bottom, a connection for the main vacuum line. As arranged in the present case, where no washing of the cake is required, fourteen of the sixteen compartments are constantly in communication with this vacuum line, eight of them being submerged in the pulp in forming the cake as they move slowly therethrough and six of them being exposed to the air, the vacuum withdrawing the moisture as far as possible during this exposure.

Where washing of the cake is required and the washings and main filtrate must be separated, an additional vacuum line is attached to the outer face of the valve, so that the last mentioned six segments are independently connected.

Of the two remaining compartments, the one adjacent to these under vacuum, registers with a vent hole in the valve and releases such vacuum as may be retained therein.

This venting arrangement has proved a very economical factor in the operation of the filter as the vacuum is not neutralized by compressed air—which would be the case in the absence of any vent—the compartments in passing the vent hole simply coming under atmospheric pressure, and the sudden shock from vacuum to pressure is thus avoided.

The remaining compartment registers with a compressed-air line attached to a suitable location in the valve and with a pressure of two or three pounds per square inch, the cake is blown off the filter plates clean.

Thus the sequence of operations, as the wheel slowly revolves.

With a three-minute revolution, the wheel is forming the cake for ninety seconds, sucking out the retained moisture for 67½ seconds, releasing the vacuum 11¼ seconds and blowing off the cake for 11¼ seconds.

But very low pressures are required to dislodge the cake owing to its partial release by the vent hole and in the case of certain materials, it may even drop of its own weight.

In any event, just sufficient water to lubricate the face of the filtros plates and allow the cake to slip off cleanly, needs to be blown back. There is but little tendency for even a very slimy cake to adhere to the filtros plates, as the surfaces are smooth and extremely rigid.

Furthermore, what little water is blown back, runs directly down the face of the wheel into the tank as

the scrapers or aprons which catch the cake do not touch the face of the wheel by one-eighth inch or so. This slight back flushing of each compartment at every revolution of the wheel keeps the filtros plates in the highest state of efficiency and as each compartment advances for submergence in the pulp, a clean bare surface is each time presented for a new cake. This feature in connection with the previous remarks respecting the general clean-up maintains the apparatus in a high state of efficiency.

The aprons or scrapers referred to are made adjustable and are attached to and extend over the top of half of the tank on each side of the wheel and conduct the cake into worm-conveyor troughs, similarly located, from which it may be conveyed to cars or stack.

These worm conveyors are driven by chain and sprocket, rotating in the same plane as the shaft which drives the wheel. The shaft of the latter carries a worm gear on the end opposite from that of the valve.

In the present installation, it has not been convenient to determine the actual horsepower required to run the wheel, but it is estimated not to exceed 1 hp, as the wheel is so nearly balanced.

In a total rotating weight of about 9000 lb., only 8 to 11 lb. are lost by removal of the cake from the discharging segment, which, with the gradual loss of moisture from the exposed segments of the wheel, represents approximately the driving power needed.

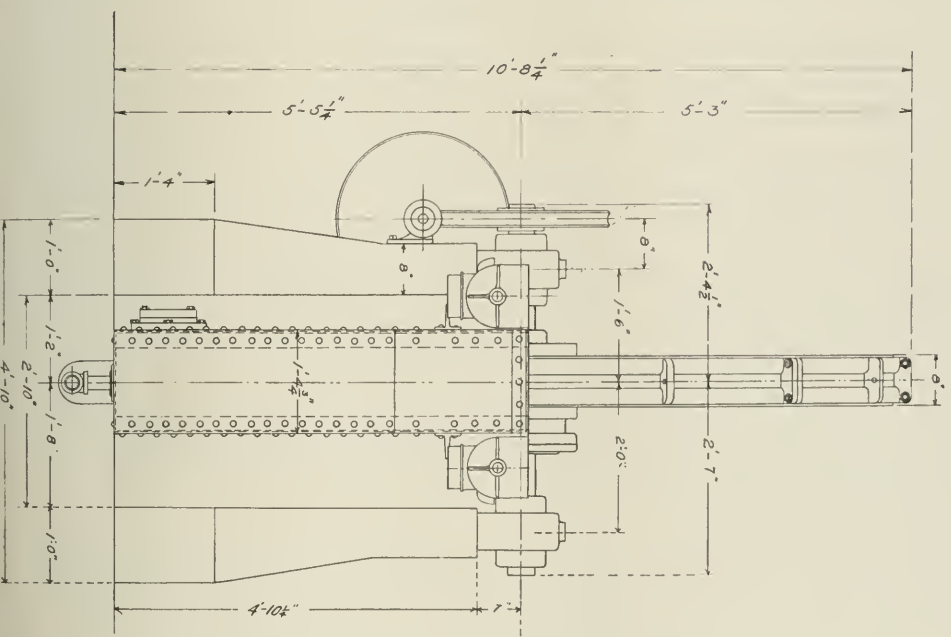

FIG. 3—SECTION OF CONTINUOUS FILTER

The worm conveyors probably require as much power as the wheel proper.

Vacuum pump power is not here considered, as this would be required with any vacuum filter.

Aside from the wear and tear on mechanical parts, the up-keep of this filter is apparently nil, as the permanency of the filtering medium removes the largest item in this respect.

The capacity of the wheel in the present instance has been difficult to estimate accurately, as the density of the feed pulp is constantly varying. The capacity is, furthermore, dependent upon so many factors that it can only be stated that from 45 to 60 tons of dry solids are being handled each twenty-four hours.

The cake was approximately ¼ in. thick at 15-in. vacuum and carried about 27 per cent. moisture; about ⅜ in. thick at 24-in. vacuum and carried 23 per cent. moisture.

In justice to the wheel, it should also be stated that the present proposition is not an ideal one, the mill tailings being filtered, showing on screen analysis but 2.5 per cent. on 100 mesh and 72 per cent. through 200 mesh. Water in contact with them requires a slight acid reaction and the finer portions are of a clayey nature and in a colloidal condition. As an illustration of what may be done under more favorable conditions, some experiments with this pulp showed that by adding one-quarter of 1 per cent. of lime, an increased capacity of 18 to 20 per cent. was obtained on the wheel. As the problem was mainly the disposition of a waste material, however, the lime treatment has not been applied yet.

The present filter wheel is but one of a battery of several to be installed at this plant and is the invention of Col. W. W. Robacher of Rochester, N. Y. The United States and foreign patents are controlled by The General Filtration Company, Inc., of Rochester, N. Y., who are making the present installation.

An Examination of Fire-Bricks

"An Examination of Fire-Bricks and Some Other Technical Refractory Materials" is the subject of a report by **W. Hamilton Patterson** in the (British) Iron and Steel Institute Carnegie Scholarship Memoirs, Vol. 6, page 231, 1914. The author considers only those refractory materials which are cheap and have therefore more general application. The ordinary fire-clays are the raw materials from which the majority of these are obtained with or without the addition of other substances, such as ganister or bauxite.

Fire-bricks made from these have wide application and are selected to suit various conditions. Three large industries may be instanced—the production of iron and steel, the manufacture of glass, and the cement industry, with special reference to the lining of rotary kilns for the making of Portland cement.

In each of these industries various conditions obtain, and the refractory material is chosen to comply with them as far as possible.

The author discusses the valuation of fire-brick in three respects:—chemical analysis, specific gravity and limit of refractoriness. Only bricks and materials which may be considered highly refractory, that is, with a melting point of 1600 deg. C. and upward, are considered.

The importance of correct ultimate analyses of clays and fire-bricks made from clays is emphasized. The author proceeded as follows: "The sample is prepared by successive grindings and quarterings, and finally passing through a sieve of at least 90 mesh. It is then, in the case of a fire-brick, dried at about 150 deg. C. to remove any accidental moisture.

"The loss of ignition on 1 gram is determined by heating over the blowpipe flame.

"Half a gram of the sample is fused in a platinum crucible with at least 2.5 grams of fusion mixture ($K_2CO_3 + Na_2CO_3$), the heating being carried out care-

fully over a small Bunsen flame and finally over a full flame.

"The melt is extracted with water and hydrochloric acid, and the whole evaporated to dryness on a water bath. It is moistened with concentrated hydrochloric acid and again evaporated to dryness. Finally, care is taken to evaporate a third time to complete dryness. This can be hastened by placing it in the air oven, but as it is not advisable to ignite the residue at a temperature of more than 111 deg. C. to 120 deg. C., the water bath alone is perhaps preferable.

"*Silica.*—The whole is taken up with hot dilute hydrochloric acid and the silica filtered off and digested with some more dilute hydrochloric acid, and finally washed with hot water until the washings are free from chlorine. This gives nearly the correct amount of silica as slight errors compensate, but its purity may be tested in the usual way by treatment with hydrofluoric acid plus a few drops of concentrated sulphuric acid.

"*Alumina, Ferric Oxide, Titanium Oxide, etc.*—These may be determined together by double precipitation with ammonia, or determined together in one portion of the filtrate, another equal portion of the solution being reduced with hydrogen sulphide, the latter expelled by boiling and passing through carbon dioxide, and finally titrating the iron with N/50 permanganate solution.

"Finally, in a part of the filtrate, usually half the amount taken for either of the above, the titanium is estimated by the well-known color reaction of Weller, by adding hydrogen peroxide, freshly made from sodium peroxide.

"If the iron and titanium are each separately determined from the alumina the precipitate is dissolved for the second time in dilute sulphuric acid instead of hydrochloric acid.

"Calcium oxide, magnesia, and the alkalies are determined by the usual gravimetric methods, the Lawrence Smith method being adopted for the alkalies.

"Titanium oxide is a widely occurring substance and yet it is remarkable that if one looks up the analysis of silicates and clays in various text-books different statements are given as to its estimation. Thus in Lunge, 'Technical Methods of Chemical Analysis,' it is distinctly stated that the titanium comes down with the silica. On the other hand, Treadwell, another authority, in his well-known book on analysis, makes no mention of titanium coming down with the silica at all, but says that it is precipitated by ammonia in the iron and alumina group. The latter statement is the more correct. The following results were obtained in the case of two fire-bricks:

"1. Total weight of silica residue obtained = 0.3643 gram, 2.06 milligrams were left after treating with hydrofluoric and sulphuric acids.

"Of this 0.0005 gram was found to be titanic oxide, which corresponds to 0.10 per cent of titanium oxide in the total fire-brick. But in the same analysis there was also found after separation of the silica as above, with the iron and alumina, titanic oxide equivalent to 1.00 per cent of the total brick.

"2. In this case 0.17 per cent titanium oxide was found with the silica and 0.76 per cent with the iron and alumina. It seems probable that the amount of titanium oxide brought down with the silica increases according to the temperature to which the silica is subjected after evaporation of the hydrochloric acid. The hydrochloric acid used to dissolve the iron and alumina, etc., from the silica after final evaporation to dryness also ought not to be too diluted."

The limit of refractoriness was determined in an electric tube furnace, using a carbon tube with a hydrogen atmosphere.

The test-pieces of the brick, which were small, pointed pieces, were placed in holes in a small graphite boat, as much pointed end projected up as possible. The softening point was recorded when the ends began to bend slightly or round at the top, but as a rule this was not measured, being rather uncertain. The melting point was taken when they collapsed. This, as a general rule, was perfectly definite, and the temperature at which it occurred could be easily defined.

The temperature was measured with a Wanner optical pyrometer. Table I is a list of some of the melting points obtained.

Analyses of some of the samples, the melting points of which are recorded in Table I, are given in Table II.

Fire-Brick for Lining Rotary Kilns.—The question of choosing suitable refractory material for the lining of the clinkering zone of rotary kilns for the production of Portland cement is of interest and importance. As the brick will have to contend against highly basic substances it might be naturally supposed that a basic brick will best fulfil the conditions required.

An examination of a brick which gave very satisfactory results in practice, however, led to the following results:—

	Deg. C.
Melting point	1735
Density	2.217

Ultimate anyalysis—

	Per Cent
Silica	73.2
Alumina	18.3
Ferric oxide	6.5
Titanium oxide	0.4
Calcium oxide	0.4
Magnesia	trace
Alkalies	0.50
Loss on ignition	0.22

The explanation of the success of such a brick for the purpose is given from the fact that it fuses on the sur-

face, and forms with a cement clinker a protective coating which prevents further attack. The question of protective coatings is thus important in judging the practical refractoriness of fire-bricks.

The investigation was carried out in the Muspratt Laboratory of Liverpool University.

A Diatom Heat-Insulating Brick

In the wall construction of furnaces, kilns, boilers, etc., two entirely different problems must be distinguished. One is to provide a refractory lining which will stand the high temperature, the chemical action of the charge, etc., without being destroyed. The other problem is to provide heat insulation, that is, to provide a lining which lets as little heat as possible pass from the inside to the outside. These are two entirely different problems and cannot be solved in general by the same material. In furnace design and construction it is usually very much better to keep the two problems separate and solve each separately, that is, to provide a composite wall consisting of a lining of firebrick or other highly refractory material next to the charge, this backed up by a highly heat-insulating brick, and this again backed up on the outside by ordinary brick.

For the purpose of heat insulation, kieselguhr or infusorial earth has been known for years to be a most excellent material (see, for instance, the extensive article on kieselguhr in our Vol. XII, page 109). But to get kieselguhr in brick form has been a problem in itself and a rather difficult one which has only been solved in recent years. For this reason the following notes on the "nonpareil insulating brick" of the Armstrong Cork Company of Pittsburgh, Pa., should be interesting.

Nonpareil insulating brick is made as follows: Bricks are formed of a mixture of kieselguhr, a small amount of clay, and finely ground cork. The mixture while wet is molded into brick measuring 9 x 4 x $2^1/_2$ inches, which are dried and then fired. The cork is first carbonized and then gradually burns out completely. In this way, the brick is subjected to uniform heat through its entire mass. The burning out of the cork leaves the brick porous in texture and a light terra cotta in color. The cubical contents of a single brick are 90 cubic inches. The weight averages $1^1/_2$ pounds. A cubic foot of the material, therefore, weighs approximately 29 pounds.

As to insulating efficiency, the heat conductivity of nonpareil insulating brick is approximately 12 B.t.u. per square foot per degree difference in temperature per one-inch thickness per twenty-four hours. The transmission through fire brick or ordinary building brick will average 120 B.t.u. Thus nonpareil insulating brick transmit one-tenth of the heat transmitted by ordinary building brick; or, in other words, the insulating efficiency of a single course of nonpareil brick 4 inches thick is equivalent to that of 40 inches of ordinary brick.

The high insulating value is due to the structure of the diatoms making up the kieselguhr, as it is composed of the skeletons or shells of almost pure silica, hollow and filled with air, and it is due to the large volume of air confined in minute particles that diatomaceous earth owes its pre-eminence as a natural heat-insulating material.

Being composed so largely of diatomaceous earth which, as just explained, is practically pure silica, nonpareil brick will withstand relatively high temperatures —much higher in fact than any other form of insulation designed for similar purposes. The fusing point is about 1600 degrees F.

Further, nonpareil insulating brick combine insulating efficiency with a sufficient degree of strength to enable their being used as a structural material. While weighing but $1^1/_2$ pounds each, they will stand a crushing load of 140 pounds to the square inch. They are just as easy to lay as ordinary brick, and in fact, are more readily shaped and cut, where fitting becomes necessary.

Another marked advantage of nonpareil insulating brick as compared with other insulating materials is its resistance to moisture. The brick may be soaked in water or subjected to steam for an indefinite period of time, and after being permitted to dry out will be found to be as strong and efficient as they were before such treatment. There need be no hesitancy, therefore, in employing them in places where they may be subjected periodically to water or dampness.

In installing nonpareil insulating brick the importance of securing continuous insulation—without breaks —should be kept constantly in mind. The brick should be laid in a special insulating cement, which is composed of practically the same substances as the brick themselves and has substantially the same insulating value. Thus nonpareil insulating brick laid with this special cement, provide a solid, unbroken wall of insulation.

As mentioned before, nonpareil insulating brick may be laid between the inside fire brick and the outside common brick, or they can be placed outside the common brick and the exposed surface finished off with a coat of cement plaster. In every case, an inner lining of fire brick must be used, for nonpareil brick are not a refractory material and will not withstand the abrasion to which fire brick are ordinarily subjected.

In recent years the Armstrong Cork Company has evolved a high-pressure covering for steam pipes which is distinctive because it is the only covering made of diatomaceous earth and asbestos. It contains no cork whatever. It is particularly well suited for the insulation of superheated steam surfaces. Moreover, it will bear repeated wetting and drying without injury and for this reason is an ideal form of covering for underground steam lines.

Further information on the use of the diatom insulating brick may be found in the bulletins of the manufacturers, the Armstrong Cork Company of Pittsburgh, Pa., entitled "Nonpareil Insulating Brick," "Comfort and Economy in the Bakery" (heat insulations of bake ovens), "Nonpareil Insulating Brick in Glass Houses," "Permanent Fortifications" (the use of insulating brick in refrigerating plants), and "Saving Fuel" (use of insulating brick for boiler settings).

Paint Remover Patent Decision

The suit of the Chadeloid Chemical Company against the Wilson Remover Company and John MacNaul Wilson for alleged infringement of the Carleton Ellis paint remover patent 714,880 of December 21, 1902, was determined last month in favor of the complainant by Judge Hand in the United States District Court, Southern District of New York. The decree grants the Chadeloid Chemical Company a permanent injunction restraining the defendants from making, using or selling the compositions in issue without license from the complainant and provides for the usual accounting of damages, alleged to have been sustained by reason of the infringement.

Judge Hand, in his decision, says that no successful paint remover had appeared when Ellis set to work. Immediately, his invention went into great use and has substantially controlled the field. All the elements exist which justify one in calling Ellis's patent a pioneer patent.

The decision discusses at some length the contention of the defendant that the "suitable solution" of the patent was not practicable. In final answer to this "it is enough to say that a paste made exactly after the directions of that example was sold under the name

of phenoid and had a successful, though limited, market. However, even if the 'suitable solution' had been very inferior it would have been immaterial if the patent had shown the road to success, as it certainly did. The commercial composition was clearly disclosed, because the patentee gives a large range of equivalents, both in solvents, waxes and alcohols."

"Having determined that the patent is broadly valid because of its basic character, the question arises of infringement. It is quite true that, put in one form, it is accurate to say that Ellis merely omitted one element of the prior art, phenol, but that is a very meagre measure for the real invention. The fact was that the art had relied upon phenol (which no one wanted), because it was at once a potent solver and a non-evaporant. . . ."

"If then it be asked at what point the percentage of phenol avoids infringement the answer is not hard; substantially at that point where the prior art supposed it was necessary, as shown by the lowest percentage it had reached. Since Ellis emancipated the art from the necessity, his monoply should extend to the degree of that emancipation."

Obituary

Charles Martin Hall, whose name will forever be remembered in connection with the foundation of the American aluminium industry, died in Daytona, Fla., on December 27, 1914. At the time of his death he was vice-president of the Aluminium Company of America, but for the last few years he had been in poor health and had been forced to retire to a degree from his formerly very active engineering and business life. As a

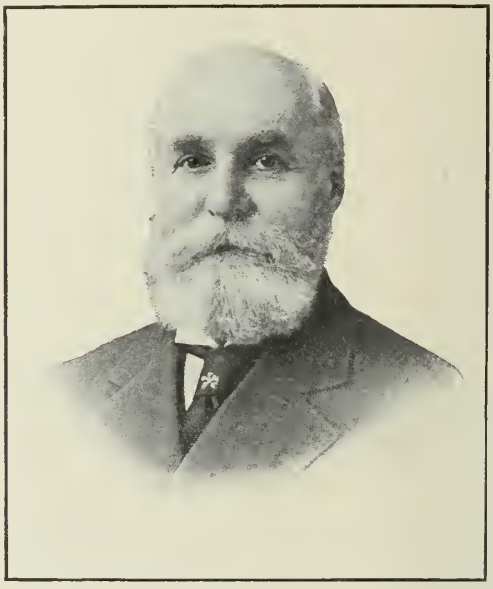
THE LATE CHARLES M. HALL

full biographical sketch of Mr. Hall was given in our Vol. I, page 10, only the principal dates of his life will be stated here.

Charles M. Hall was born at Thompson, Geauga County, Ohio, on December 6, 1863. His father was a congregational minister, and moving to Oberlin in 1873, young Hall attended the public schools there and later Oberlin College. There he had one term of chemical study with Professor Jewett and was so captivated with the subject that for nearly a year thereafter he experimented in the Oberlin laboratory, with the special object of finding an electric method of commercially producing aluminium. His experiments were first crowned with success on February 23, 1886, his chief invention being the electrolyte now universally used. Heroult had made simultaneously and independently the same invention in France. To carry out Hall's process, the Pittsburgh Reduction Company was formed in 1888 and began turning out aluminium commercially in November, 1888. The further development of the aluminium industry is history. When Hall started, aluminium was worth about $25 a pound. Hall's later inventions all had some relation to the aluminium industry. He improved especially methods of purifying alumina, baking carbon electrodes, etc. He received the honorary degree of LL.D., from Oberlin College in 1910, and the following year he was awarded the Perkin gold medal from the allied chemical societies of this country. Mr. Hall made his home at Niagara Falls. He was a bachelor.

* * *

Theodore Armstrong, president of the Pennsylvania Salt Manufacturing Company, died on January 5, at his



THE LATE THEODORE ARMSTRONG

residence in Philadelphia, aged 71 years. He had been in failing health for some time. He was born in New York and served in the army during the Civil War. After the close of the war he obtained a position to audit the accounts of internal revenue collectors in Philadelphia and neighborhood. Soon after he became connected with the Pennsylvania Salt Manufacturing Company, and later was appointed chief accountant of the company's works at Natrona, Pa. Seven years later he was made chief auditor at the Philadelphia offices of the company and later became successively secretary, treasurer, vice-president and president. He was chosen president in 1888, and had since held that office. Under him, the management of the company was practically reorganized and many improvements made in its operation and general business, constituting it one of the foremost concerns of its class in the country. Mr. Armstrong was also president of the Wedge Mechanical Furnace Company and a director in several other companies. He had been, for several months, too sick to attend to business and Joseph Moore, Jr., was chosen president pro tempore to perform his duties. He was a member of the Society of Chemical Industry, the American Chemical Society, the National Geographical Society and of many clubs and societies in Philadelphia, where he leaves many devoted personal friends.

Concrete Pumps

Reinforced concrete pumps are the subject of quite an interesting new invention of Mr. Henry De Huff of Philadelphia. They are furnished built complete in place by the D'Olier Centrifugal Pump & Machine Company of Philadelphia, or, if desired, this company furnishes the necessary iron parts and reinforcing bars with complete drawings for the concrete work. This invention is of especial interest in connection with very large capacity pumping projects such as dry docks, drainage and irrigation work. The concrete construction renders practicable the use of pumps of larger capacity that have heretofore been practicable, so that pumps having a discharge connection 10 feet in diameter or larger can be built. The pump is provided with stationary rings with which the pump impeller forms a close clearance and these rings serve as anchorage for the reinforcing bars and a means of centering the concrete. We reserve a more detailed description for our next issue.

Personal

The Anaconda Copper Mining Co. has made some changes in its technical staff recently. Mr. **Frederick Laist** will be metallurgical manager for the plants at Great Falls and Anaconda, having supervision over construction and technical matters. He is succeeded as general superintendent of the Washoe plant by Mr. **L. V. Bender,** who has as assistant Mr. **H. S. Ware.** The business of the Great Falls and Anaconda plants will be in charge of Mr. C. W. **Goodale** and Mr. **E. P. Mathewson** as heretofore.

Mr. Albert Burch has resigned his position as general manager for the Goldfield Consolidated Mines Co., being succeeded by Mr. **J. W. Hutchinson.** The position of assistant general manager vacated by Mr. Hutchinson will be filled by Mr. **K. M. Simpson.**

Mr. **Noel Cunningham** is engaged in professional business in the southwest, with headquarters at Douglas, Ariz.

Mr. **A. E. Drucker** has gone to Colombia to build a cyanide mill for the Frontino & Bolivia Gold Mining Co.

Mr. N. V. Hansell, of Hamilton & Hansell, 50 Church Street, New York, sailed on Saturday, the 23rd inst., for Europe. He expects to visit England, Russia and the Scandinavian countries before returning to New York.

Mr. **G. J. Kapteyn** has gone to Colombia as superintendent of the cyanide mill of the Bar Principal Mining Co.

Mr. **O. M. Kuchs** has been promoted from assistant superintendent to superintendent of the Toledo smelter of the International Smelting & Refining Co.

Messrs. **John D. Ryan, Benjamin B. Thayer** and **C. K. Kelley** of the Amalgamated and the Anaconda copper companies were in Great Falls, Mont., on a trip of inspection of the smeltng and refining property and conference regarding its future.

Mr. **W. G. Swart** has accepted appointment as consulting engineer for the Hardinge Conical Mill Company, devoting only a part of his time to his new duties and retaining his connection with the American Zinc Ore Separating Company in Denver.

Mr. **C. C. Titus,** manager for the Northwest Metals Co., of Helena, Mont., has been spending several weeks in Denver.

Mr. **Charles S. Witherill** has gone to Chuquicamata, where he will act as general superintendent of the reduction plant of the Chile Exploration Co. He was formerly superintendent of the copper department of the Balbach Smelting & Refining Co. He will be assisted by Mr. **L. M. Green** in charge of leaching, with Mr. **M. R. Thompson** in charge of the electrolytic tank house and Mr. **Otto Koch** in charge of smelting and melting.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Electroplating (Concluded)

672,074, April 16, 1901, George D. Burton, of Boston, Mass.

Relates to an apparatus in which currents of electricity are used in connection with a saponaceous fluid for cleansing cloth, wool, cotton, yarns, or other articles; and it consists in applying to a tank containing a suitable detergent solution, electrical conductors for electrolyzing and heating the solution. The apparatus consists of a tank containing an inner adjustable compartment, having perforated walls, and within which are the articles to be cleaned. Adjacent the ends and bottom of the inner compartment are conductors, so proportioned that a part of the current flows through the conductor, thereby heating the solution, and the remaining part passes from one end conductor through the solution to the other end conductor. The current passing through the solution is said to act on the solution and the articles and cleanse and improve them. The solution may be water, or a weak solution of sal-soda, borax, concentrated lye, or other saponaceous or alkaline liquid.

678,383, July 16, 1901, Ferdinand Eppler, of Berlin, Germany.

Relates to a process of metal ornamentation, by undercutting grooves for inlaid work, and depositing metal in the undercut grooves. The grooves may be partly filled with strips of wire cloth, which effects an economy in metal deposited; and when the grooves are cut in nonconducting material, such as granite, etc., the strips of wire cloth serve as conductors. A number of ways are suggested for securing the conductor, and also to produce ornamental effects.

687,386, Nov. 26, 1901, Botho Schwerin, of Munich, Germany.

Relates to the extraction of sugar from saccharine matter, such as beet-root, sugar-cane, sorghum, and the like, by the electric current. The substance containing the sugar is disintegrated, or finely subdivided, and enclosed in a wet state between a porous diaphragm and a permeable electrode connected as cathode; the anode is placed within a compartment containing water, with a body of water between it and the diaphragm. Upon passing the current, acidic elements are transferred to the anode compartment, while water, alkaline components, and soluble albumen compounds, together with the sugar, pass through the permeable cathode. It is stated that the electric current does not "invert" the sugar. The sugar is separated from the liquor containing it, and from the other substances present, by known methods.

688,857, Dec. 17, 1901, Warren Johnson, of New Orleans, La.

Relates to correcting the weights of metal blanks for coins, etc. In practice, the blanks vary in weight, some are too heavy and others too light. The heavy blanks are placed in a holder and connected as anode, the lightweight blanks being connected as cathode, and both im-

mersed in a suitable electrolyte, the current removing the excess metal from the anode and depositing it upon the cathode; or the blanks may be connected up with ordinary anodes and cathodes to correct their weight.

691,803, Jan. 28, 1902, William F. Patton, of Toledo, Ohio.

Relates to making seamless hollow spheres for floats for steam or water traps. A hollow sphere of paraffin is first made by pouring melted paraffin in a sectional mold and rotating the mold to form the paraffin sphere. After cooling the paraffin sphere is removed, a connecting nipple attached, and the sphere coated with plumbago and "iron by hydrogen," after which it is immersed in a solution of copper sulphate to give it a chemical deposit of copper. It is then electroplated to the desired thickness, the electrodeposit making a firm joint with the connecting nipple. After electroplating the paraffin is melted and run out through the nipple.

694,658, March 4, 1902, Jules Meurant, of Liege, Belgium.

Relates to processes of electrodepositing metals, and to electrolytes in which "addition agents" are added. A variety of addition agents are mentioned, including carbohydrates, organic acids, gums, gelatine, etc. Specific examples are given for zinc, tin, nickel, copper, and silver. With zinc, it is stated that a steel tube, zinc plated, was crushed and then folded upon itself without the deposit stripping. The patent should be consulted for details.

703,857, July 1, 1902, Constantin Jean Tossizza, of Paris, France.

Relates to a process of electrodepositing metals, such as zinc, nickel, cobalt, and cadmium, from solutions containing sulfurous acid, which consists in electrolyzing a solution of zinc sulfate with copper anodes, requiring a minimum voltage of 1 1/10 volts, up to about 1 5/10 volts, with a current density of 40 amp per square meter. The solution containing copper sulfate, after charging with sulfurous acid, is now separately electrolyzed with insoluble anodes, requiring a minimum voltage of 31/100 volt, up to about 5/10 volt. The acid liquor obtained, sulfuric acid, is used to dissolve more ore. Taken together, the two operations permit the electrolysis of zinc at a voltage which is the sum of these two operations, a minimum of 1 4/10 volts, and with acceptable current densities, about 2 volts. See patent No. 710,346.

705,456, July 22, 1902, Duncan Sinclair, of Coalbrookdale, England.

Relates to producing an iridescent coating upon copper, bronze, or like surfaces. The article is first thoroughly cleaned, then connected as an anode and suspended in a solution made of 14 oz. of caustic soda, 10 oz. litharge and ½ gal. of water, boiled for one hour, and then diluted to a gallon. To the above solution is added a small proportion of copper-plating solution, which is made as follows: dissolve 1 lb. of potassium cyanide in 1 gal. water, suspend a weighed copper anode sheet therein and pass a current from the copper until the solution contains 3 oz. of copper to the gallon. A current is passed from the copper article to be made iridescent as anode in the above solution for a time and at a current density depending upon the graduation of color desired. When this is reached, it is taken out, thoroughly dried, and may be subjected to heat varying according to the effect desired, from 150 deg. Fahr. to 500 deg. Fahr. The heating intensifies the color of the iridescent coating which is said to consist of an oxide of lead containing copper.

710,346, Sept. 30, 1902, Constantin Jean Tossizza, of Paris, France.

Relates to electrodepositing copper from the sulfate solution resulting from the treatment of roasted copper ores with sulfuric acid. The sulfate solutions thus obtained contain besides copper, sulfate of iron, and other metals. During electrolysis, the voltage tends to rise, resulting in the depositing of other metals, and finally spongy iron. The present invention relates to electrolyzing such impure solutions with carbon anodes, and depolarizing the same with sulfurous acid, either as a gas or liquid, which may be passed into a hollow anode, or over the outer surface thereof. The sulfurous acid is oxidized to sulfuric acid, and reduces the voltage required to electrodeposit the copper, with working current densities, to 6/10 volt. The sulfurous acid is obtained by roasting sulfid ores. See patent No. 703,857.

713,277, Nov. 11, 1902, Anson G. Betts, of Lansingburg, N. Y.

Relates to electrodepositing and refining lead and its alloys. The electrolyte described in his prior patent, No. 679,824, dated Aug. 6. 1901, is used, to which is added a reducing agent, such as gelatin, pyrogallol, resorcinol, saligenin, ortho-amido-phenol, hydroquinone, and sulfurous acid. Of these gelatin is the cheapest and gives the best results. One part of gelatin is dissolved in hot water and added to 5000 parts of solution. A current density of 10 to 20 amp per square foot of cathode surface is used. A product is easily made with a specific gravity of 11.36, the same metal remelted and cast having the same density. With higher current densities the lead becomes harder and more brittle. A sample deposited with a current density of 40 amp per square foot showed a specific gravity of 11.276. The presence of the reducing agent serves to restrain crystallization of the deposit. Gelatin and pyrogallol give projections that are nodular on thick deposits. See patent No. 713,278.

713,278, Nov. 11, 1902, Anson Gardner Betts, of Lansingburg, N. Y.

Relates to electrodepositing and refining lead and its alloys, and claims the product produced by the process described in his co-pending application, which became patent No. 713,277.

716,306, Dec. 16, 1902, Otto Carl Strecker, of Cologne, Germany.

Relates to preparing printing plates by electrolytic etching. The plate properly prepared and coated with a resist is connected as an anode in an electrolyte, which for a zinc plate may be a 2½ per cent solution of fluoride of sodium, a current density 0.5 amp to 0.9 amp per square foot being used for from two to five minutes. The patent should be consulted for details.

Book Review

Laboratory Course in Electrochemistry. By **Oliver P. Watts**, of University of Wisconsin. 150 pages, 16 illustrations; price, $1. New York: McGraw-Hill Book Company, Inc.

This book contains in abridged form directions for 133 experiments illustrating elementary principles and some advanced principles of the electrolysis of solutions and of fused salts. Electric furnace operations and detailed electrochemical analysis are not considered.

The dominant idea of the book is to guide students into observing and understanding the real principles involved in electrolysis. Assuming, of course, that they have a competent and enthusiastic instructor, Dr. Watts' book is admirably suited to its purpose. It is clear, direct, stimulating to observation and thought, and puts more weight on principles than on details, on contriving with simple apparatus than on merely using expensive special apparatus. We heartily commend the book to all beginning work in the electrochemical laboratory.

Copper and the Flotation Process

One of the most suggestive points in Mr. Mathewson's notes on present tendencies in copper metallurgy, published elsewhere in this issue, is the effect of concentration by flotation. From its position as an intermediate process between gravity concentration and smelting, flotation exerts an influence in both directions. In ore-dressing it has proved the method par excellence for concentrating slime. Hence the production of slime in crushing and grinding for gravity concentration is no longer the bugbear that it has been in recent years. A natural conseequence is an increased production of fine concentrates unsuited to blast furnace treatment, but reverberatory smelting removes any difficulty on this score. The efficiency of flotation, plus the improvements in reverberatory smelting, is modifying milling ideas by reducing the upper limit of size at which gravity concentration has been practiced. The combination points to more fine grinding and slime concentration, and the relegation of the blast furnace from its eminent position.

Another interesting possibility is the effect of flotation on leaching processes. At a time when hydrometallurgy is just getting its stride and finding acceptance among metallurgists, flotation rises as a definite competitor and threatens the popularity of copper leaching. Progress in flotation is being made so rapidly that the actual application of leaching processes may halt to await developments. With such results as flotation has shown at Anaconda it may be a question whether the elaborate roasting-leaching process developed there will be long continued. In the case of oxidized copper ores also, flotation may forestall leaching if the process of converting carbonates and oxides to sulphides, and floating the latter, is successfully developed. Further, while leaching may be profitably applied to certain ores, the character of ore-bodies changes with depth and oxidized ores give place to sulphides or mixtures which will be unsuited to leaching but may be amenable to flotation.

Flotation is still in the empirical stage of development. Its success in one place is no criterion of the possible results at another. Its usefulness must stilll be determined wholly by experiment, varying the conditions as to oil, acid, temperature and combinations of these elements. But enough has already been done to show that it is a tremendous factor in ore treatment and that opportunity still awaits the investigator. When the horizon of the flotation process is happily clear of the clouds of legal patent litigation, progress should be more rapid and knowledge more widely disseminated.

The War and American Iron Trade

The European conflict has exerted a very slight influence upon the general course of the iron trade of the United States. The result is quite opposite to the expectations entertained in many quarters last August, when predictions were made of a rapidly expanding export trade, or quite contrary expectations entertained in other quarters in September and October, that business in the United States would be so paralyzed that there would be no domestic demand. Indeed, the whole course of events has been to illustrate in striking manner the unwisdom of making predictions when one is not acquainted with the circumstances.

Last August the view was very commonly expressed that here was the golden opportunity for the United States to build up a large export trade in iron and steel. It was unfortunate that we had not captured the trade already, but here was the opportunity to make up for lost time. The experience of only a few months has shown that if the United States had had a large export trade it would have suffered more severely than it did, for in the past few months the total demand for iron and steel among all the non-producing countries has been but a small fraction, probably less than one-quarter of what it was before the war. With Germany, Belgium, and France practically out of the competition, England's iron and steel exports have decreased by about 40 per cent, and the exports of the United States by about 20 per cent, even though in the case of the United States the exports have been swelled somewhat by demand for war material.

The immediate effect of the war was a stringent curtailment of iron and steel demand in the United States, but the demand in the past two or three months has been decidedly better and if the current demand is continued for two or three months longer the domestic demand in the United States for the full period since the war started will be approximately as large—or as small—as it was in the corresponding period before the inception of the war. The American iron trade was already in a state of almost acute depression.

In one respect there is still the possibility of the war having an acutely unfavorable influence upon the American steel trade, this possibility arising from the ferromanganese situation. Several months ago England placed an embargo upon the exportation of ferromanganese, subject to certain limitations which it was supposed would be easily met. American steel manufacturers were asked to sign an agreement that if they should receive English ferromanganese they would not export steel to certain designated countries, but the concerns that signed the agreement are still awaiting shipments. They have lately been approached with a fresh proposition of "marrying contracts" by purchasing additional ferromanganese at $68, in return for which they will be furnished equal tonnages of the alloy on their old contracts, made at from $35 to $38. The dollar looms so large in the negotiations that there now seems little doubt but that American steel makers will be able to secure ferromanganese when they are ready to pay the price.

There is another question, of magnesite for basic open-hearth furnace use, hitherto imported from Austria, but no serious apprehensions are entertained on that score. Altogether, the American iron and steel industry has suffered wonderfully little dislocation as to its raw materials and supplies from the European war, and there is much cause for congratulation that it proves to be so almost completely self-contained.

Taking Care of the Human Element

The passing from "first aid" to "safety first" is typical of the increasing attention now being paid by mining and metallurgical companies to the welfare of the human element in their operations. Just as they are now seeking to prevent accidents and avoid injuries by anticipating their possible occurrence through preventive measures, rather than offering remedial aid after accidents have happened, so also are they forestalling dissatisfaction and eliminating labor troubles by administering to the social welfare of their employees.

Seldom has any humane movement found such ready and world-wide acceptance as has been accorded to "safety first." Following less rapidly in its wake has come the less pretentious but equally important welfare movement for better sociological conditions. Perhaps the sequence is natural. Physical injury or fatal accident obtrudes itself on our attention, and its cost is definite and tangible. Social malaise and discontent cannot be expressed mathematically; and because it makes a less broad and striking appeal to human sympathy, its ill effects on industry have not been so apparent.

The good work of the pioneers in welfare work, however, has sharpened the perception of the great majority of large operators. Consideration for the human element, wherever it has been conscientiously observed, has been shown to yield tangible results in continuous and faithful service and efficient performance of duty. It has created the spirit of pride and loyalty so essential to the maintenance of effective organization, so that instances are not lacking where contented employees have been deaf to the arguments of unwise agitators. In fact, it has been apparent that by anticipating the welfare of employees, stimulating and directing their mental and social activities, prudent companies have forestalled dissention and avoided labor troubles.

The welfare work of the Homestake company in South Dakota is a conspicuous example. Under the direction of the late Thomas J. Grier, this company has shown commendable interest in the life and activities of its employees. Among the institutions established by the company is the hospital, the service of which is free to employees and their dependents. One thousand dollars monthly is contributed to an aid fund, to which the 2500 employees add one dollar each per month. This fund provides accident, sick and death benefits. For the wholesome amusement and recreation of employees, a large hall was erected by the company at a cost of $300,000. This contains also the Hearst free library.

Co-operation between industrial companies and the Y. M. C. A., which has been so effective in railroad work,

has been of benefit to mining companies. By agreement with this organization, companies are enabled to provide a social center for employees and their families, affording a place to spend time profitably and away from vicious influences. Such centers ultimately supply all the social needs of the community, as well as affording educational facilities. The Bunker Hill & Sullivan company has established at Kellogg, Idaho, an industrial Y. M. C. A., erecting a building at a cost of $35,000 and contributing $1500 annually to its support. Members pay an annual fee as in similar institutions elsewhere. This center serves at once as a social club, a meeting place for the labor organization and a night school. It is equipped with gymnasium and baths, billiard and game rooms, bowling alleys and public library. That it warrants support and has contributed materially to the welfare of employees, is the testimony of company officials.

Examples could be multiplied. The Copper Queen company in Arizona administers an employees' benefit fund to which it makes an annual contribution of $7500. This voluntary association of employer and employees has been found useful in spite of the adoption in Arizona of a compulsory workmen's compensation law. The Hollinger company at Porcupine adopted over a year ago a system of "loyal service" bonuses to day-wage employees without distinction save as to term of service. In 1914 this bonus amounted to nearly $12,000. It is based on a graduated scale of remuneration according to the term of employment. Men in service for over a year receive a bonus of fifteen cents per day; over two years thirty cents and over three years forty-five cents. At most of the large mines and metallurgical works that have come into existence during the last few years, some sort of provision has been made for the welfare and prosperity of the employees. In most cases the isolation of mine, mill or smelter has made necessary as well as advisable, the maintenance of clubs, places of recreation, model and sanitary homes, and participation in various kinds of benefits.

The Pyrophoric Alloy Decision

The final decision in the pyrophoric alloy litigation, as rendered by the United States Circuit Court of Appeals and printed elsewhere in this issue, is of considerable importance to the chemical industries, and particularly to those manufacturing alloys, both because of the chemical questions which it settles and the legal doubts which it terminates.

Considering the latter point first, the claim of the Welsbach patent involved in the litigation was for a pyrophoric alloy containing cerium alloyed with iron, while the specification mentioned nickel and cobalt as alloying metals, and also spoke of using iron or its equivalent, in making the alloy. The legal question was as to whether the claim of the patent, naming specifically only iron, was competent to cover any other alloying metal or metals; or, generalizing the question, as to whether a claim covers more than it specifically names, and may be extended to their fair equivalents. On this point the court rules that the patent being a pioneer invention is entitled to a liberal application of the doctrine of equivalents, which does not confine a patentee to equivalents which he has expressly referred to, but allows him any other fair equivalents unless he has himself restricted his claim by some statements in his specification. The specification of the Welsbach patent did indeed state that one of the metals in the alloy must be a rare-earth metal, among which metals cerium was relied on as essential to the composition of the alloy, thus restricting the claim on the cerium side; but the specification placed no restriction upon the other constituent, the iron side of the alloy, other than to specify that it must be a non-rare-earth metal; that is, not be a metal of the rare-earth class. This negative restriction led the court to the conclusion that each and every metal not of the rare-earth class must be considered as a fair equivalent for the iron in the Welsbach alloy, as long as it acts in a similar manner when alloyed with cerium. This extension of the field of a claim of a basic patent to cover all fair functional equivalents, even when not specifically named, and even when the claim does not speak of equivalents, is the first important point of the decision.

The second point, the chemical question at issue, was as to whether the term "equivalent" should mean, in the case of this alloy, as concerned the term "iron or its equivalent" in the specification, an element chemically related to or chemically equivalent to the iron, or should connote equivalency of function, or equivalency of result when used in the alloy. The respondent had strenuously urged that the equivalency in question must be regarded as chemical equivalency, and the metals replacing iron be limited to the metals associated with iron in the periodic system, such as nickel, cobalt and possibly manganese. The complainant, however, urged that such chemical equivalency had no meaning in the field of alloys and was absolutely without certainty or value in determining equivalency in producing a given desired result or property of an alloy. This position and principle were accepted without reserve by the court, which ruled that the equivalency of other metals with iron is to be found not in their chemical structure, but in their functional efficiency when combined with cerium in a metallic alloy. If this ruling is generalized it means that in an alloy, or in fact any chemical compound, protected by a patent, the "equivalent" of any claimed ingredient of the same is another element which acts functionally and with efficiency to create the same valuable property of the product, to an industrially useful degree. Such a functionally equivalent element may or may not be chemically related to it, or chemically in the same family of elements; whether it is or not is not the determining factor in considering equivalency in the sense of patent law. The law considers only functional efficiency; that is, capability, of acting to a useful extent, to produce the same result.

Owners of chemical and metallurgical patents and prospective applicants for the same should mark, learn and inwardly digest this interesting decision, because of its fundamental bearing upon the scope and meaning of "equivalents" in this class of patents.

Readers' Views and Comments

The Action of Fluorspar on Basic Open-Hearth Slags

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In your issue of January, Mr. W. S. Hamilton proposes a theory to explain the great effect additions of fluorspar have upon the fluidity of basic open-hearth slags. There is no necessity of resorting to speculation, as the research of Karandief, published in the *Zeitschrift für Anorganische Chemie*, 1910, LXVIII, 188, has shown that $CaSiO_3$, melting at 1501 deg. C., forms an eutectic, with 38.2 per cent CaF_2, which freezes at 1130 deg. C.

Examination of Fire Bricks

To the Editor of Metallurgical & Chemical Engineering.

Sir:—I feel that a comment might be in order on the determination of titanium, as referred to under the title "An Examination of Fire Bricks," by W. Hamilton Patterson, in your February issue.

A procedure that I have found to give excellent results, with comparative ease of operation, is modelled largely after the method described by W. F. Hillebrand in Bulletin No. 422, U. S. G. S. The weight of silica previously obtained is corrected for the total residue, after treating with hydrofluoric and sulphuric acid. The precipitate containing aluminium, iron, etc., is then weighed in the crucible still containing this residue. Two or three grams of potassium pyrosulphate are then added and the alumina precipitate is dissolved in the fusion.

The melt is dissolved in dilute sulphuric, and any silica which has come down with the alumina remains insoluble. This should be weighed and added to the previously found weight of silica.

Care should be taken not to use too much heat in dissolving the melt, as titanium is sometimes precipitated if present in large quantities. The solution may then be split into two portions, determining iron in one and titanium in the other; or, if the iron is determined by zinc reduction and permanganate titration, titanium may be determined in the solution after this titration.

This method takes care, almost automatically, of the possible impurity of either the silica or alumina precipitate and insures the presence of all of the titanium in the sulphuric acid solution, whether or not any of it has been carried down previously with the silica.

Fused Silica Dishes for the Concentration of Sulphuric Acid

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In your January issue there is an article by Mr. William Mason on the concentration of sulphuric acid in cascade-type plants using fused silica dishes.

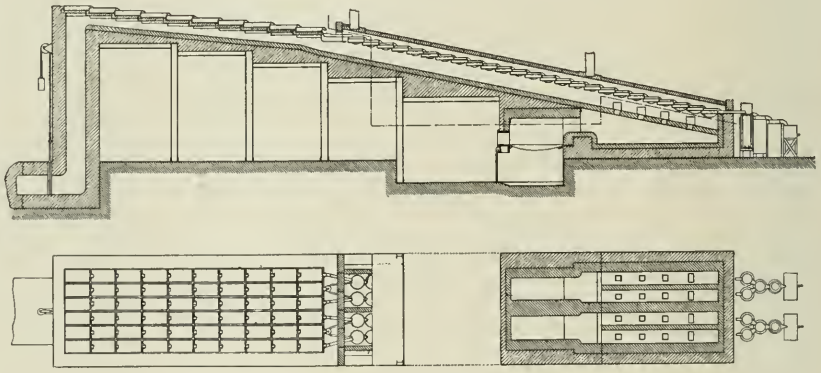
The description of the concentrator and the conclusions which are drawn are not applicable to the standard type of plant in general use, and as the production of concentrated sulphuric acid either from chamber acid or by-product acid, resulting from nitrating processes, petroleum treatment, etc., is of considerable interest at the present time, I would request the courtesy of space in which to outline the history and present status of fused-silica-dish-type concentrators.

The genesis of continuous cascade concentrators is undoubtedly the continuous glass retort system patented by Henry Chance in 1871. This system, which was in extensive use in England for many years, consisted of four or more glass retorts arranged in cascade, over a gas or coal fired furnace. The retorts were provided with glass connections, so that the weak acid fed into the top retort could flow through the other retorts, meanwhile undergoing gradual concentration. The acid drawn off from the last retort was led into a cooler, and thence into storage tanks or carboys.

The breakage of retorts was a serious figure in the operating costs, but the system survived owing to its low installation cost compared with platinum.

Attempts were made about 1887 to replace the glass retorts with porcelain, but the porcelain retorts were costly and gave no better results.

The next development came in 1889 when Négrier built a furnace, using porcelain dishes in place of the retorts, and a fume chamber of acid-proof brick over the dishes in place of the top of the retort and its connecting pipe. The Négrier furnaces were of small capacity and were superseded about 1900 by the Benker and Hartman system which made use of forty-eight porcelain dishes combined with a set of lead pans to utilize the waste heat and incidentally to carry the concentration from 50 deg. Beaume to 58 deg. Beaume.



PLANT FOR CONCENTRATION OF SULPHURIC ACID

The Benker and Hartman system gave fairly good results, but the breakage of porcelain dishes was a frequent cause of trouble, while the fuel efficiency was lower than other types of concentrator which came into use about the year 1906.

With the invention of vitreosil (fused silica) in 1906, and its development toward apparatus of commercial size in 1907, the cascade concentrator system took on a new lease of life, so that at the present time there are more vitreosil units in use throughout the world than any other type of concentrator.

The introduction of vitreosil dishes removed the two most serious faults of the porcelain concentrators, excessive breakage and low fuel economy, and enabled the design to be improved by substituting a single fire in place of the three used on the Benker-Hartman plants.

The breakage of porcelain dishes was caused through uneven heating or the slowing down of the feed and chilling of the dish when the feed was turned on full

again. By reason of its low coefficient of expansion (0.54×10^{-6} or one-sixth that of porcelain) vitreosil dishes do not break through temperature changes no matter how severe, as is well evidenced by the usual lecture-room experiment of plunging a white-hot vitreosil crucible into cold water without breakage occurring.

Occasionally in the operation of vitreosil concentrators, the feed has been accidently shut off, the acid boiled out of the dishes, and then the full feed turned on again into the red-hot dishes without a dish being cracked.

This resistance to temperature changes permitted the vitreosil dishes to be directly exposed to the fire gases in open seatings, instead of being protected with 2-in. fireclay slabs, which, of course, gave a greatly increased fuel economy.

The position of the firebox and the type of furnace has been a source of continual experiment and the plus pressure furnace referred to by Mr. Mason has been tried out by two factories only, as it was not found possible to get the temperature regulated over the whole length of the concentrator.

Natural-draft furnaces burning soft coal have given the best results and are in general use. Furnaces burning fuel oil and natural gas are also used, but the construction is similar to the soft-coal furnaces.

The illustration on page 136 shows the general outline of a unit to produce 20,000 lb. 66 deg. Beaume per twenty-four hours from 50 deg. Beaume H_2SO_4 and shows clearly the furnace position and arrangement of firing flues. This unit contains 100 dishes (12¼ in.) and sixty pans (24 in. by 12 in.) used in place of lead preheating pans. All the pans and dishes, excepting the last three in each row at the exit end of the plant, are supported in open seatings and are directly exposed to the fire gases. The last three dishes have closed seatings, as experience has shown that with open seatings at this point, the acid boils strongly, with loss of SO_3 and spurting of liquid on to the seating. The breakage of lower basins referred to by Mr. Mason was in all probability due to the use of open seatings. The acid spurted over would come into contact with the seating and the asbestos rope gasket, and gradually form a solid mass. The contraction of the seating with a slight cooling of the plant, would break the basin unless it was free to rise and fall on its gasket, as the relative coefficients are as 1 is to 14.

Units such as shown in the cut will concentrate 50 deg. Beaume H_2SO_4 to 66 deg. Beaume, with an average fuel consumption of 17 per cent of 13,000 B.t.u. soft coal, consumption being based on the weight of finished acid. The breakage of dishes in fifteen factories for which accurate records are available, has always been under 5 per cent per annum from all causes, while the failure of preheater pans is less than 1 per cent per annum.

The first silica-basin concentrator was installed in 1907 and at the time of writing upward of 500 complete units are in use throughout the world, thus indicating the value of the vitreosil dish system.

A considerable proportion of these plants handle recovered acid containing traces of nitric or organic acids, as vitreosil is attacked only by hydrofluoric acid.

Within the last year several units have been put up for the continuous concentration of solutions, either containing free acid or substances which will attack iron, lead, etc., and providing the solution is run off before crystallization takes place, excellent results can be obtained.

Quantitative Blowpipe Analysis

To the Editor of Metallurgical & Chemical Engineering:

Sir:—Returning from a two months' trip to Panama and the West Indies, my attention has been attracted by the two well-written and instructive articles on the above subject by Mr. Fischer, in your November and December issues, 1914. Mr. Fischer does not exaggerate unduly the usefulness of these aids to the prospector, but he has exaggerated somewhat my personal contribution to the advance of this art. I refer particularly to being credited with devising the useful little scale of alloys of gold and silver. This was devised by my own instructor in the art, Dr. Victor Goldschmidt of the University of Heidelberg; my own contribution was merely the suggestion of a brass case with screw top to ensure safe carriage of the scale in the prospector's kit.

"Limitations of the Electric Furnace in the Manufacture of Steel Castings"

To the Editor of Metallurgical & Chemical Engineering:

Sir:—On page 110 of your February issue Mr. G. Muntz, in the article of "Limitations of the Electric Furnace in the Manufacture of Steel Castings" refers to my article in *The Iron Age* of March 27, 1913, as one which contained statements which were the products of enthusiasm and at variance with actual facts. Not one word of evidence was given to substantiate this statement and no statement in my article was even mentioned.

Mr. Iver Rennerfelt, on page 582 of your September issue, quoted me correctly and gave the facts that are recognized by nearly all metallurgists. Those that know about the manufacture and casting of steel know that the Bessemer converter was a wonderful invention for cheapening the manufacture of steel and giving it a field of usefulness that it did not have before that time. No one argues that the Bessemer converter makes as good steel as the open-hearth furnace. Likewise no metallurgist claims that the open-hearth furnace makes as high-grade steel as the crucible or electric furnace in commercial quantities. Metallurgists also know that the converters, used in steel foundries, are modifications of the Bessemer process and cheapen the production of steel castings but do not improve their quality.

The most foolhardy foundrymen would not attempt to use the steel coming from a converter to cast the wheels, with hollow spokes and rims, which I illustrated in that article in *Iron Age*, and guarantee them to be absolutely free from blow holes. Wheels that were 24 inches in diameter were cast with walls but ⅛ of an inch thick and with ½-inch fillets where the spokes join the rims. Only ⅛ in. was allowed for finishing the face and sides of the rims and the hubs.

In that article I described, in detail, why such castings could not be made commercially from steels melted and refined in converters, or even in open-hearth furnaces, and yet Mr. Muntz did not mention even one of these, to say nothing of refuting them. Not being retained by any steel maker or furnace builder, I was free to express all the facts that my investigations presented. Anyone capable of appreciating it, should be enthusiastic over a fine piece of work. That is positively no argument against the facts I gave as to how these castings were made, or how they could and could not be made.

In the *American Machinist* of Dec. 13, 1908, I described and illustrated some steel castings made by the Flexilis Works in Germany that were even better than

these. An exhaust manifold for an automobile engine was cast by them in lots of 500. It was 22 inches long with a 1½-inch pipe. Its center was water jacketed with a ½-inch space and an outside diameter of 2¼ inches. All the walls were cast 3/16 of an inch thick and the flanges were given ⅛ of an inch finish. Steel cylinders 12 inches diameter and 18 inches long, with outside ribs, were cast with ¼-inch walls. All the fillets were ¼-inch and the finish on the cope end was but 3/16 of an inch. Many other castings of a similar nature were shown and they were all guaranteed to be entirely free from blow holes.

They would also cast them from any steels with any carbon content desired and also from any of the high-grade alloys.

This story was doubted and called enthusiasm by American foundrymen using converters and open-hearth furnaces until an American foundry, using crucible furnaces and the German methods, began to market a similar product. It would be suicide for any foundrymen to attempt to make steel castings to such specifications, at a commercial price, from converters or open-hearth steel. Blowing air through iron to reduce the carbon content to that of steel, as the converter does, cannot reduce the oxides, nor does it reduce the sulphur and prosphorus to as low percentages as will be found in steels coming from the crucible or electric furnaces.

Metallurgists that have not become commercialized will not claim that these and other impurities can be commercially reduced to as low percentages in converter steel as in those made in crucible, electric or even open-hearth furnaces.

I do not want to be misunderstood by the thought that I am condemning the converter entirely. Modified Bessemer converters, either of the Bradley Stoughton or Tropenas type, have been of great benefit to the steel casting industry and will continue to have a large field of usefulness. But when one tries to argue that they make better steel than the crucible or electric furnaces he expresses things that are at variance with the vast amount of data that have been compiled nnd published about steels in the past few years. Some very high-grade steels can be made in the open-hearth furnace by using three or more slags for purifying the metal and materials that act as scavengers, but this adds considerably to the cost and might make the steel more expensive than that which is made in electric or crucible furnaces. Likewise, more time and materials might be used to make converter steel of a higher grade than is now the case, but the impurities cannot be removed as thoroughly as by the processes used in other furnaces. Where cost is a big factor the converter becomes a very important tool, but when quality is the main consideration other furnaces give better results.

Detroit, Mich. E. F. Lake.

Tube-Mill Tonnage Calculation

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I was much interested in Mr. A. H. Jones' very complete discussion of my tube-mill tonnage formula, in your February issue. I should have pointed out in my original discussion in your January issue that any mesh can be used as the basis of the calculation; thus it can be based upon plus 28-mesh as Mr. Jones has done in his illustrative calculation.

I instanced minus 200-mesh, as to most millmen "per cent. minus 200" carries a distinct meaning; knowing the minus 200 one can reconstruct the approximate screen test of any normal ore, and no other size gives the same general information. The numerical expression for ratio of tube-mill tonnage to battery tonnage, based upon the plus 28-mesh from Mr. Jones' screen tests is:

$$\frac{T}{B} = \frac{d-a}{c-b} = \frac{0-41.8}{0-21.8} = 1.91$$

as he correctly calculates it. However, if his sampling and screen tests are accurate, the same formula applied to his minus 200-mesh should give the same ratio. The numerical expression based upon minus 200 in his screen tests is

$$\frac{T}{B} = \frac{d-a}{c-b} = \frac{72.3-21.2}{28.1-6.5} = 2.39$$

I have tabulated below Mr. Jones' screen tests with an added column giving the ratio of tube-mill tonnage to battery tonnage as calculated for each size of screen by my formula.

Table II from Mr. A. H. Jones' Discussion

Mesh	Battery Discharge Per Cent a	Tube-Mill Feed Per Cent b	Tube-Mill Discharge Per Cent c	Dorr Overflow Per Cent d	Ratio Tube-Mill Tonnage to Battery Tonnage $\frac{d-a}{c-b}$
10	10.3	5.4	....	....	1.91
14	10.0	5.2	....	....	1.92
20	10.2	5.3	....	....	1.91
28	11.3	5.9	....	....	1.92
35	7.7	4.9	1.0	....	1.97
48	7.1	6.5	3.1	....	2.09
65	5.6	8.1	6.5	....	3.50
100	6.0	20.0	20.0	1.0	....
150	6.6	24.4	28.6	12.5	1.40
200	4.0	7.8	12.7	14.2	2.08
—200	21.2	6.5	28.1	72.3	2.37
				Average	2.11

It will be noted that the individual calculations do not check very well, and my experience has been that screen tests from samples taken over a period of only a few hours are very apt to be misleading. Segregation is the salient feature of the tube-mill-classifier closed circuit, and a very slight adjustment of the batteries may introduce irregularities which take hours to become readjusted. Samples taken carefully over a considerable period of time will give approximately the same calculated ratio of tube-mill to battery tonnage for each mesh.

For this purpose, daily routine sampling is best, the samples being taken by the mill crew and the screening being done in the laboratory. One has a check on the accuracy of the work by applying the formula to each mesh.

I regret that I have not with me at this writing any screen test records. Certainly publication of a series of screen tests such as Mr. Jones gives, for a number of mills, would be a very valuable addition to technical literature and would throw an interesting light upon the milling of various ores.

Douglas, Ariz., Feb. 16, 1915. Noel Cunningham.

The Western Metallurgical Field

Platinum Milling in Wyoming.

In our issue of February 1911, page 75, was described the concentration of platiniferous ore at the Rambler mine in Wyoming. The work as then described was continued for some time, but the mill was subsequently closed and a period of inactivity followed. Several months ago, however, work was renewed by the Platinum Mining & Milling Co., an organization of stockholders under the management of Mr. Julius Thielman, which leased the property. For the past two months the 50-ton mill has been in operation, concentrating the dump ore, and the first shipment of concentrate was to have been made during February. According to Mr. Robert A. Marr, metallurgist for the company, the concentrate contains platinum, palladium, iridium,

osmium, gold, silver and copper. At the rate of milling, the dump contains sufficient ore for one year's operation, and there is still ore in the mine which will be kept in reserve.

Several interesting changes have been made in the milling system since the work was described four years ago. Chief among these is the use of a Peck centrifugal concentrator. This machine is of a different type than the one used experimentally at Anaconda. The latter was of the vertical type, while the one under consideration is horizontal. The ore is ground to 60-mesh in a Hardinge pebble mill working in closed circuit with a drag classifier, the oversize being returned for regrinding. Following the drag classifier is a 60-mesh screen which finally limits the size of the pulp particles. Its principle function, however, is to remove wood pulp or other foreign matter that would interfere with the operation of the concentrator. The Peck horizontal-type centrifugal concentrator is the only one of its kind in use, and handles the entire product of the crushing department, producing concentrate and tailing. In order to insure a pulp of uniform density for the concentrator feed, the ground ore is kept in agitation in a tank fitted with paddles.

In the early operation of the mill considerable difficulty was encountered from the acidity of the ore. Some of the copper occurs as sulphate, and there are other soluble forms. The mill water, becoming impregnated with acid copper salts, corroded screens and metal work throughout the mill, causing delays and increasing cost of operation. In order to overcome this difficulty the present management is adding from five to six pounds of lime per ton of ore at the crusher, so that the mill water is alkaline. This corrects not only the acidity of the ore, but also of the mine water which is now being used for milling.

Milling Results at Magma Copper Mine.

The Magma Copper Company, developing a large low-grade copper mine in Arizona, has had in operation at the mine a mill of 150 tons daily capacity for the purpose of testing milling methods. A combination of water concentration and oil flotation is in use. The recovery of copper, including ore sorted by hand, has averaged over 85%. During the year ended December 31, 1914, shipments of picked ore and concentrates amounted to 5474 tons, averaging $1.90 gold and 22 oz. silver per ton, and 20% copper. The product has been hauled by teams about 32 miles to Florence, Arizona; but at present a narrow gage railroad is under construction from the mine to Webster, a point on the Arizona Eastern Railroad, about 31 miles from the property.

Quicksilver in Nevada.

The Nevada Cinnabar company has recently begun the treatment of mercury sulphide ore at its mine at Ione, Nevada. The main feature of the plant is a 50-ton Scott continuous roasting furnace, with supplementary equipment in the form of condensers and refinery. The ore is crushed to 1½ in., dried in a rotary dryer and then charged in the furnace. The temperature is maintained at about 1000°F. Mercury distills and passes from the furnace through side ports to a dust chamber and thence to the condensers. Of the latter there are eight independent sets of two chambers each, connected by terra cotta pipes. The condensers are cleaned through doors suitably arranged. About 30% of the mercury recovered runs from the condensers, but the remaining 70% is retained by heavy carbonaceous matter or soot. The entire product from the condensers is moistened and placed in a pan that is heated to a low temperature by means of steam. The mixture is then worked with a hoe which causes the mercury to coalesce and run free from the soot. A rotary machine designed to perform this operation mechanically is soon to be installed. The condensed product from the last few sets of condensers contains considerable moisture. In the treatment of this product, ashes, lime or other dry alkaline material is added in order to reduce the moisture content and at the same time cut the greasy film that prevents the globules of mercury from running together. Altogether about 90% of the mercury condensed is recovered, and the balance together with the soot is recharged to the furnace in small quantities. As the plant has been in operation only a short time, and no complete clean-up has ben made, it is impossible to indicate the percentage of extraction.

Federal Mining Experiment Stations.

A bill introduced in the House of Representatives by Congressman Foster, chairman of the House Committee on Mines and Mining, and known as House Bill 15869, has been passed by that body. It provides for the establishment of ten mining experiment stations and fifteen mine safety stations in the several important mining districts of the United States and Alaska, under the direction of the Bureau of Mines. The function of the mining experiment station is to investigate conditions and suggest improvements in the mining industry, preventing unnecessary waste of resources, and generally contributing to the advancement of the industry. No appropriation is mentioned, but it is understood that $750,000 will be required to make the act effective. Provision is made, however, for accepting "lands, buildings or other contributions from the several States offering to co-operate in carrying out the purposes of this Act." It now seems possible that the bill will be passed by Congress at this session. It would have been better if the sum of $750,000 could have been placed at the disposal of the Bureau of Mines without making it necessary to dissipate a considerable portion of the sum in the maintenance of so many stations; but it appears politically necessary to accept these conditions in order to make an entering wedge for some federal support to mining.

Company Reports

The Wellington Mines Co., operating mine and mill at Breckenridge, Colo., makes the following report for the year ended November 30, 1914. Developed ore amounts to from 45,000 to 50,000 tons, containing from 4 to 5% lead and 17 to 18% zinc. The wet concentrating mill was idle during six months of the year, and was thoroughly overhauled, the capacity being increased to 125 tons daily. The magnetic mill also was closed during April for repairs. A Hardinge ball mill and another magnetic separator have been added to the equipment, giving a better recovery of both lead and zinc. The wet concentrating mill treated 17,430 tons of ore, averaging 17.4% zince and 4.98% lead, producing 1106 tons of concentrates assaying 34.8% lead (dry), and 9145 tons of middlings assaying 24.13% zinc, 2.46% lead and 27% iron. The magnetic mill treated 8172 tons of this middling, producing 3657 tons of concentrates assaying 46.14% zinc and 83.9 tons of lead concentrates assaying 64.1% lead. In addition to this, the magnetic mill treated during the first five months of the year 6820 tons of middlings assaying 18.62% zinc and 3.44% lead, producing 2028 tons of 47.75% zinc concentrates and 161 tons of 65.2% lead concentrates. The tailing from the magnetic mill carries 53% iron and some gold, silver and lead, but it cannot be marketed on account of high freight rates.

Nevada Consolidated Copper Co. has issued its

fourth quarterly report showing the production for the year 1914.

The copper output during the four quarters was as follows: 15,597,592 lb; 14,322,807; 11,258,421; 8,065,-236. During the fourth quarter the property was operated on a basis of 50% normal capacity. The tonnage treated was 416,825 and the grade 1.54% copper. The cost of copper, crediting miscellaneous earnings, was 8.42 cents per pound. After payment of the 20th dividend, there was a deficit for the quarter of $378,949. The physical assets of the Steptoe Valley Smelting & Mining Co. having been acquired by Nevada Consolidated in August 1914, the former was legally dissolved in November 1914.

Chino Copper Company's report for the fourth quarter of 1914 shows a production of 8,935,585 pounds of copper, as compared with 17,288,678 pounds in the first quarter. The average daily tonnage treated in the fourth quarter was 3774 as against 6469 tons in the first quarter. The total copper production for the year 1914, including copper contained in crude ore shipped, was 56,841,977 pounds. The average grade of ore treated in the fourth quarter was 1.8612% copper as against 2.1653% for the third quarter. The average extraction was 69.14%, as against 68.04% for the previous quarter. The ratio of concentration was 19.82 to 1. The cost per pound of copper, without allowing credits from other sources, was 8.14 cents. Credit for gold amounted to 0.12 cents per pound. With all miscellaneous earnings credited, the cost per pound was 7.71 cents.

Ray Consolidated Copper Co. shows a production of 9,563,113 pounds of copper during the fourth quarter of 1914, as compared with 17,707,374 pounds in the first quarter. The ore milled during the quarter amounted to 402,917 tons, averaging 1.74% copper. Average mill recovery was 68.2%. Milling costs were 54.56 cents per ton, compared with 45.85 cents for the previous quarter, the increase being due to the decreased tonnage. Average coarse crushing cost was 2.666 cents per ton, and mining cost 49.722 cents. Net cost of copper was 8.748 cents per pound; crediting miscellaneous income it was 8.645 cents.

Utah Copper Company's fourth quarterly report for 1914 shows a production of 20,229,012 pounds of copper, as compared with 40,017,562 pounds in the second quarter. The gross production for 1914 was 121,779,-401 pounds; for 1913, 119,939,809 pounds. The quantity of ore milled in the fourth quarter was 1,035,303 tons, all at the Magna plant. The average grade of the ore was 1.5062% copper. Extraction was only 64.86%, as compared with 68.13% in the previous quarter. The reduction was due to carbonate of copper in the ore. The average cost of copper for the quarter was 7.731 cents per pound, crediting miscellaneous income it was 6.688 cents. The financial statement shows a deficit for the fourth quarter of $142,293.

The Wolverine Copper Mining Co., Michigan, gives the following data on operation in the annual report for the year ended June 30, 1914. Ore stamped amounted to 182,127 tons, from which 4,606,015 pounds of mineral was recovered, yielding 3,435,459 pounds of refined copper. Cost per ton of ore stamped, $1.92; cost per pound of refined copper at the mine, 9.85 cents; total cost refined copper, 11.3 cents per pound.

The annual report of the **Coniagas Mines Ltd.**, Cobalt, Canada, for the year ended October 31, 1914, states that the year was not so profitable as the preceding three years, owing to the low price for silver, the diminishing output of high-grade ore and the dislocation of business due to the war. No valuable discoveries were made on outside claims staked by the company. The annual bonus to employes at Christmas time amounted to 4% of their annual earnings, or $8,682. The concentrating mill treated 54,522 tons of ore, averaging 24 oz. silver per ton, at the rate of 2.93 tons per stamp. High-grade concentrates shipped amounted to 496.4 tons, averaging 2030 oz. silver per ton; low-grade slime amounted to 251.8 tons, averaging 151 oz. Mine ore shipped amounted to 493 tons averaging 2944 oz. Sand tailings from the mill averaged 3.18 oz. silver per ton, and slime tailings 6.66 oz. It is estimated that the ore reserves contain 14,880,000 oz. silver.

From the report of the **Mount Morgan Gold Mining Co.**, Queensland, Australia, for the half-year ended November 29, 1914, the following data are taken. The concentrator handled 31,274 tons, recovering 87.4% of the copper and 77.5% of the gold. The smelter treated 179,939 tons. The production was 4593 tons of refined copper and 58,309 oz. gold. The new smelting furnaces were started in July, two being in operation and one held in reserve. Some difficulty has been experienced in handling flotation concentrates, but experiments have indicated a solution of the problem, which, however, is not stated in the report.

The annual report of the **Hollinger Gold Mines, Ltd.**, of Ontario, Canada, shows that $2,688,354 was recovered from milling 208,936 tons of ore of an average value of $13.67 per ton. The gross profits amounted to $1,786,-680. Dividends paid amounted to $1,170,000. The mill was in operation 92.2% of possible running time, and handled an average of 633 tons per 24 hours of running time. The stamp duty was 13.30 tons per 24 hours. Chemical consumption per ton of ore: cyanide, 0.525 lb.; lime, 1.557 lb.; zinc, 0.532 lb.; acid, 0.216 lb.; lead acetate, 0.0031 lb. Average value of pregnant solution, $5.698. During the year there was stacked for retreatment 6062 tons of concentrates of an average value of $8.85 per ton. The rapid development of the property has necessitated enlarging the mill, and it is expected that 100 stamps will be dropping by the middle of March 1915. Continuous decantation has been adopted for a considerable tonnage of ore treated. Distribution of milling cost is as follows, based on total tonnage treated and including 2910 tons of ore milled for the Acme company. If based on Hollinger ore only, 208,936 tons, the cost is $1.22 per ton.

Present Tendencies in Copper Metallurgy

BY E. P. MATHEWSON
General Manager, Anaconda Copper Mining Company

Finer Grinding in Ore Dressing

In ore dressing, the flotation process is finding a vast field in sulphide copper ores, particularly those in which the sulphide minerals are finely disseminated. Numerous processes, so-called, are being placed on the market and a great variety of flotation machines. A number of these machines have given marvellous results, giving a tailing as low as 0.08 per cent copper, this having been obtained in continuous runs lasting for several weeks and representing thousands of tons of material. Strange to say what was considered impossible a few years ago, namely, the concentration of slimes by flotation processes, is now accomplished without any difficulty whatever.

The wonderful improvements in the reverberatory smelting of copper ores, to be mentioned below, have changed the ideas of millmen, so that coarse jigging will soon be abandoned, and nothing will be jigged coarser than $\frac{3}{8}$ of an inch size.

The material for flotation seems to concentrate better in proportion to the fineness to which it is ground. In many mills 60-mesh material is the coarsest that is sent to the flotation machines.

In roasting concentrates, the furnace of the McDougal type seems to have the preference. There are several styles of these furnaces on the market, and all seem to be giving good results.

Reverberatories Superseding Blast Furnaces

The introduction of oil fuel, followed a few years ago by the successful use of pulverized coal on reverberatory furnaces smelting roasted copper concentrates, has revolutionized reverberatory construction and practice. The latest furnaces are 25 ft. by 144 ft. inside dimensions and have a capacity of from 700 to 800 tons daily, with a fuel ratio of better than 7 to 1. A still larger furnace is now in course of construction that will measure 175 ft. by 25 ft. inside. This furnace is for the purpose of treating hot converter slags with raw copper concentrates in order to recover the copper in the slags and to make a slag clean enough to be thrown away. This furnace is estimated to have a capacity of over 1100 tons daily. Of course a greater part of the charge will be molten slag.

The fuel economies from the use of pulverized coal are astonishing. With a grate-fired furnace, and a similar furnace using the same coal in pulverized form, the fuel ration in the first case will be $4\frac{1}{4}$ to 1; and in the latter case, 7 to 1. The tonnage smelted by the pulverized fuel furnace is practically double that smelted by the grate-fired furnace. These economies will result in the relegation of the blast furnace (in a great many plants) to the smelting of extremely refractory ores, or it will cause their abandonment altogether, as the reverberatory furnace in most localities will be able to do the work at about 75 per cent of the cost of blast-furnace operation. Of course, there are some ores that it will be cheaper to treat in blast furnaces.

In blast-furnace practice the tendency is to enlarge the furnaces, and the types of furnace that may now be had give entire satisfaction, certain improvements having been introduced in recent years so that while the length of the furnace may be increased indefinitely, the size of the unit is not increased at all, as one part of the furnace may shut down for repairs while the rest of the same furnace may be kept in operation. The largest furnace at present in operation is 87 ft. long and 56 in. wide, inside measurements at the tuyeres. This furnace has smelted in 24 hours over 3300 tons of charge.

Basic-Lined Converting

In converting, the basic-lined converter is rapidly displacing the acid-lined shell, and the size of the converter is being increased proportionately to the capacity of the plant, up to a maximum of the vertical (or Great Falls) type of converter, of 20 ft. inside diameter. The vertical type of converter is preferred at most of the large smelters; the objection to the horizontal cylindrical type being the necessity for the numerous openings, in the larger converters, for the introduction of silicious material and the difficulty of getting uniform temperature, and agitation of the charge throughout the converter. In the 20-ft. vertical Great Falls type of converter there is no difficulty whatever in these matters. All new converters are operated electrically instead of hydraulically.

Another branch of copper metallurgy that is receiving a great deal of attention at present is hydrometallurgy, or leaching. Enormous plants are being constructed in various parts of the world to handle low-grade ores that are oxidized, or partly oxidized; and also to recover copper from old tailing dumps in which the copper has become oxidized.

Losses Minimized

Great attention is being paid to the recovery of valuable metals from fumes and from flue dust, and a modern plant must be equipped with apparatus for saving these metals. The Cottrell electrical precipitation apparatus seems to be the most suitable for copper-smelting operations; although with some ores, particularly those carrying zinc, the bag-house has been successfully introduced for this purpose, following the practice of lead metallurgists.

The economical handling of materials to and from the furnace is now brought nearly to perfection.

In conclusion the modern tendencies in copper metallurgy can be summed up in these words: Increased recovery in ore dressing: increased recovery of metals formerly lost in smoke and fume: reduced cost of operations, due to the introduction of larger smelting units and mechanical means of handling materials to and from furnaces: the introduction of pulverized coal as fuel for reverberatory smelting furnaces.

Anaconda, Mont.

Magnesium

The Aviation Materials Corporation has been incorporated under the laws of New York State to engage in the business of manufacturing metallic magnesium.

The corporation will operate under the patents of George O. Seward and F. von Kügelgen, the process having been developed by them at the Virginia plant of the Virginia Electrolytic Company.

Mr. George O. Seward, 99 Cedar street, New York City, is the president and general manager of the Aviation Materials Company. Work has been started on a plant to turn out ten tons of metallic magnesium monthly and the corporation expects to have the metal for sale inside of three months.

The **Joseph Dixon Crucible Company** of Jersey City, N. J., has just issued a new edition of the booklet "Dixon's Graphite Crucibles." In addition to a preface and the table of crucible sizes, information is furnished of steel melting crucibles, file crucibles, crucible covers, tilting furnace crucibles, retorts, bottom-pour crucibles, stirrers, skimmers, dippers and self-skimming crucibles. Some good advice is given in two pages entitled "For Oil Furnaces" and "General Hints" on the scalping of crucibles, use of fluxes and use of tongs. Foundry facings and a highly refractory cement for the repair of worn or cracked firebrick are also described.

Concentration by Crushing and Screening at the Vindicator Consolidated Mill

The new crushing and screening mill of the Vindicator Consolidated Gold Mining Company in the Cripple Creek district was put in operation Oct. 15, 1914. The object of the process employed is to increase the profit from the mine by treating the waste ore that formerly went to the dump. It is characteristic of many Cripple Creek ores that mechanical enrichment can be produced by simply crushing and screening, saving the finer and rejecting the coarser portions. This affords a simple method of concentration that will yield profitable smelting products from otherwise waste rock. The ultimate profit per ton is not great, but amounts to a considerable sum on a large daily tonnage. The cost of a mill is small compared with that of a concentrating and cyaniding mill such as is adapted to Cripple Creek ores, and the process probably can be applied to ores of too low grade to be treated profitably by the more elaborate process.

The former practice at the Vindicator was to sort the mine ore, shipping the first-class product to smelters and washing the waste in order to recover fine rich mineral adhering to the surfaces of the rock. The extent of the sorting process and the quantity of ore rejected from run-of-mine product is indicated in the last annual report of the company, wherein it is shown that of 76,295 tons of crude ore hoisted, 26,343 tons of shipping ore was sorted, leaving roundly 50,000 tons of waste rock to be thrown on the dump. The problem at the Vindicator was to devise a

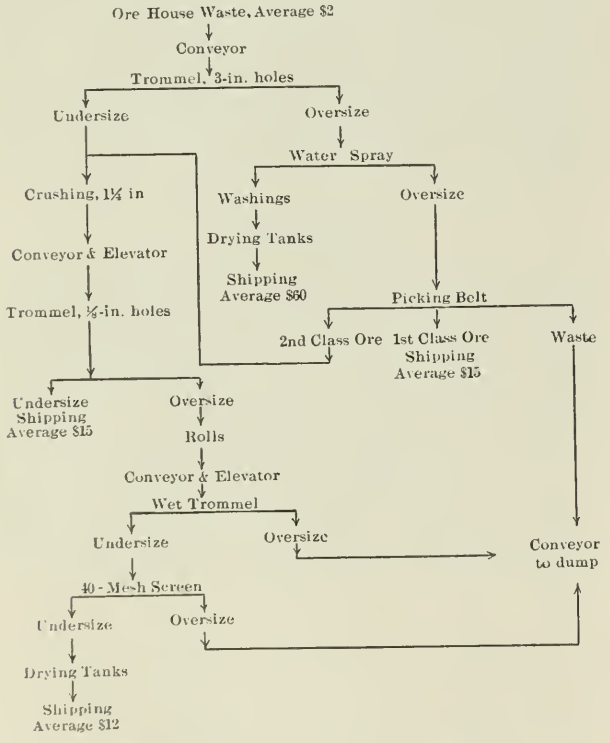

FIG. 1—FLOW SHEET VINDICATOR SCREENING MILL

profitable method of treating this ore-house waste, for the simple expedient of washing the waste and recovering fine mineral was not wholly satisfactory. Accordingly experiments were begun in 1913, under the direction of Mr. Edward S. Wiard, of Denver, to see what improvement could be made.

Preliminary Tests

Early tests indicated that the waste was capable of enrichment by crushing and screening. Experiments by jigging and tabling also showed good results, but not sufficiently high to warrant the consideration of such a process. The complete testing work involved many experiments in crushing, sorting, screening and washing,

FIG. 2—VINDICATOR SCREENING MILL

with separate assays of the various products. From these tests data were obtained showing quantities and values, and affording a basis for intelligent design of a mill. The plant as finally built cost roundly $34,000, and is reported to be treating about 400 tons daily.

The flow-sheet of the mill is given in Fig. 1, and a view of the plant in Fig. 2. The ore-house stands at the left of the mill in Fig. 1, being connected herewith by a conveyor that delivers waste rock from the picking-belt in the ore-house to a large trommel screen in the mill. The first section of the trommel screens out 3-in. rock and delivers it to the second-class ore bin. In the second section of the trommel the remaining rock receives a wash of water sprayed under 50 lb. pressure. The rich washings are delivered to settling tanks, and are shipped after drying. The trommel oversize is delivered onto a sorting-belt from which first-class shipping ore is easily picked by hand after the washing it has received. Second-class ore also is sorted and combined with the trommel undersize. The final waste from sorting falls onto a cross conveyor and is discharged to the dump.

The second-class ore is then crushed to 1¼-in. size and elevated to dry trommels fitted with ⅛-in. screen. The undersize of these trommels is a shipping product, and the oversize is retained for a second crushing in rolls to ⅜ in. The roll product is then washed in a wet trommel which serves merely as a scalping screen for the Bunker Hill 40-mesh screen which follows. The wet-trommel oversize is discarded, but the undersize is further screened on a Bunker Hill screen of 40-mesh, the oversize of which also is discarded. The undersize is a shipping product and is delivered to a settling tank and then dried. Thus the process comprises a preliminary wash, crushing in two stages with intermediate dry screening and final wet screening at ⅛ in., and 40-mesh, respectively. The values of the several concentrates are shown on the flow-sheet.

The arrangement of the plant is simple and convenient. The screens and picking-belt are placed in the top of the building, above bins and tanks which receive

the various products. All of the waste rock rejected from the picking-belt and screens is delivered to a common conveyor leading to the dump. The crusher and rolls are placed below their respective bins, and discharge their products onto conveyors leading to the two elevators that serve the dry and wet trommels.

The annual report of the company, dated Jan. 1, 1915, states that the new mill "has not been in operation at this time long enough to make any positive assertions, but the indications are that it will prove to be a very profitable investment." Judging from the care taken in the preliminary tests, the mill should add to the general profit of the company.

The Radium Situation

BY WARREN F. BLEECKER

The Standard Chemical Company of Pittsburgh was the first company with sound finances to seriously enter the radium business in the United States. Indeed there were scientific men in our own state, who, during the year in which this company was founded, seriously doubted that radium occurred in carnotite ores in commercial quantities, if at all. There were, in this country, no men who could determine radium quantitatively with any degree of accuracy and there were no metallurgical engineers trained in the treatment of the ores.

This is the problem, among others, Mr. Flannery has had to face, and how well he has done it the record of the last year has shown. Being a man of tireless energy, remarkable foresight and business ability, and associated with some of the best capitalists of this rich eastern country, Mr. Flannery carefully laid the foundation of a permanent business, the first of its kind in this country and the largest of its kind in the entire world.

The first step was the obtaining of property both by outright purchase and by location according to the laws of the land. As is well known, the Standard Chemical Company obtains its supply of raw ore from the south-western part of Colorado. When this company first came into the field the country was practically a wilderness; miles of roads were built, streams were bridged, homes were erected and employment furnished to hundreds of men and teams, thousands of dollars were expended monthly in salaries, wages and supplies. The problems of mining and transportation in this district are as great and no greater than in any other district of like isolation and remoteness from settled centers and supply bases. I do not mean, of course, that the Standard Chemical Company discovered radium in Colorado or that the country had never been entered by civilized man any more than a certain government official meant that he had discovered radium by having his photograph taken at the mouth of one of our tunnels, although the newspaper reports so stated. I wish to point out, however, that the real pioneer work of the development of radium mining, in the Paradox region, was done by private capital and that more than one million dollars had been expended in mines and processes before any cognizance or recognition of the work was taken up by the government.

After the development of mines, the building of roads and of camps, finally came the shipping of large quantities of raw ore, then of almost unknown value, to Pittsburgh. Then came the erection of the plant in which the experimental work was to be done. Following this was a long siege of costly experimental work; the training of engineers and scientists in the reduction of the ores, quantitative determinations of the values therein, the refining of the crude material into marketable products and the building up of a selling organization.

Any one who is familiar with the pitfalls which are confronted at every step in the building of a large business, using known methods, and producing standard materials, will at once realize what it has meant to found an establishment with unknown raw materials, untried processes for treating them, and with no market demand for the products.

Radium itself, considered in the light of its weight in pounds and ounces only, is a metal of almost fabulous value. When it is seen that it may be necessary to treat 1 ton of ore to obtain 1 mg of radium, it will be seen that the metallurgist is removing one part of material which he can never see, feel, or recognize by any of his natural senses, from one billion parts of foreign matter. Further, this one part must not be lost although it is carried through a maze of chemical reactions, in expensive and sometimes fragile apparatus, until it is relatively pure and ready for refining. When it is further realized that the loss of one drop of liquid, under some conditions, would result in the loss of several hundred dollars worth of radium, some conception may be had of the difficulties involved in removing this element from the raw ore and its subsequent refinement.

During the last two years, certain persons have prevailed upon a branch of the national government to assist them in entering the radium business, not in competition with, but to the ultimate exclusion of, the producers now in the field. So far as the general public know, this is purely a government enterprise. My understanding is that it is not purely a government enterprise, but an arrangement on the part of private individuals, for government backing, in order to obtain a monopoly of the radium business. This is not a logical proposition because the production of radium does not differ, *per se*, from the production of steel, copper or gold.

We should be justly alarmed should the government take over our smelters, refineries and reduction works; but we would indeed have further cause for unrest should the national government, in addition to taking over these things, put them in the hands of certain favored private individuals—under any working agreement —for a division of the spoils. While the legality of this procedure is very doubtful, we may be quite sure that it is without precedent in the history of our country.

It is a fundamental law of business that any enterprise is hazardous if the supply of raw material is limited. The hazard is greatly increased if the supply of raw materials is entirely shut off. As we all know, a mine is a mine; every pound of material removed from it makes the mine capable of producing so much less— it is not an inexhaustible storehouse of wealth. Therefore, when our mines are worked out we must look for others, and if they cannot be obtained we must go out of business. This applies to any industry which is engaged in the reduction and refining of materials taken from the surface of the earth. The government proposes to limit our raw material to that which we already have and, in this way, has set the date for our retirement just as definitely as if they had given us so many days or months to operate.

It has been stated that the Standard Chemical Company now controls or is trying to control the radium industry by acquiring all of the radium deposits. Were it not that the past few decades have seen the growth of trusts and monopolies, and that the people as a whole are prone to believe an accusation of this sort, thrown broadcast by any and all persons, responsible or irresponsible, it would be idle to mention this subject. As a matter of truth, the Standard Chemical Company now owns and controls less than one-half of one per cent of the known radium deposits in the section in which they are operating.

This is not a matter which effects merely the Standard Chemical Company or my personal interests in the matter; it effects not only the development of the state of Colorado, which unfortunately has suffered too much already by outside interference in her affairs, but further than this, it is a matter of national and international importance. To Colorado one must look for the world's supply of radium, and if properly conserved, there is enough to supply the world. If, on the other hand, the ores are withheld or their values are wasted by crude and improper methods of treatment, whatever value radium may have will be lost and this generation at least will derive no benefit therefrom.

Assuming that the government intends to enter the radium field, seriously, there are several practical problems which will be apparent to sensible people and which are of fundamental importance.

In order to produce radium, one must have mines. These the national government can easily obtain either by withholding undeveloped lands or by confiscation. Then the mines must be worked under the direction of competent engineers. In order to mine efficiently, one must do it scientifically; scientific mining requires training and skill. Trained mining engineers are, as a rule, men who command good salaries for their labor. No one has ever complained, I believe, of government scientists being over-paid. Those who propose that the government can produce radium without mining it as well make a virtual acknowledgment of business incompetency, because the business is hazardous enough when one is assured of his supply of raw material.

I do not mean by this to cast reflection upon the scientific investigations made by government men in this or any other research which they have undertaken or may undertake. The business men, however, are compelled to recognize the difference between men of purely scientific attainments however profound, and the application of these things to a bank account. Scientific research is one thing and operation is another.

The problem that the national government would face in reducing carnotite ores is no greater nor is it less than that faced by a private individual or corporation. Be it said that the working out of this problem requires a faith without limit, business management of the highest degree, and sufficient reserve funds, to carry the experimental work over and through many dark and stony places.

It is a human failing, that the things we know the least about appear to be done with the greatest ease. It is not surprising, therefore, that private individuals, or government officials, should regard the reduction of carnotite ores as a problem quite on a par with the reduction of other ores of a seemingly similar refractory nature. The chemical reactions of the various elements which constitute carnotite ore are known to a limited extent, but the relations of these elements in the ore, and the difficulty of maintaining economical methods of chemical separation, present unusual difficulties which are not overcome so easily as might be expected.

The Austrian government has for some years been in the radium business. The ores available for their use are the richest which can be found or which can be hoped for. With this tremendous advantage, which America can never hope to have, the price, even with such improvements in their processes as the Austrian scientists have been able to devise, has gone up in that country instead of down. Further than this, any one who has attempted to purchase radium from the laboratories of the Austrian government have suffered delays of many months because of the exceedingly slow rate at which the radium is being produced.

Should I be in error as to what the government has already done, in the treatment of carnotite ore, it is due to the fact that their work has been carried on under a veil of secrecy and mystery. It was stated, however, (I am willing to be corrected on this and other points in which I may be in error) that about one year ago, there was available for the so-called government plant in Denver a quantity of ore of about 1000 tons containing about 9 grams of hydrous radium bromide. What was to be done with this radium after its extraction, I have no positive knowledge excepting that there were reports that it was to be divided between government and certain private individuals. It was also stated that the government process, for the extraction of the radium of this ore, had passed the experimental stage some time during the winter or spring of last year. I do not know the proposed rate at which this ore was to be treated but have heard that it was to be of 5 tons per day.

Recently the radium produced during the year's operation was introduced at a hearing before the Congressional Committee in Washington, D. C. The quantity of radium was stated to be 170 mg; this, however, was on the basis of hydrous radium bromide and the radium content would therefore be 53 per cent of this or 90 mg of radium element. It was stated that this radium had been produced from the treatment of 220 tons of the ore mentioned above, in addition to some 1900 lb. of exceptionally high-grade ore which had been purchased quite recently. Assuming that this 220 tons of ore treated was not selected as the poorest ore that could be obtained, it would contain, on the basis of 9 mg of hydrous radium bromide per ton, 1980 mg. Nineteen hundred pounds of 30 per cent ore should contain about 116 mg of radium bromide. Therefore, there seems to have been extracted 170 mg out of 2096. The efficiency of this process is, therefore, 8.6 per cent. No organization in the world, excepting a government organization could afford to operate a plant with an efficiency of 8 per cent.

The Bureau of Mines of the United States Government has endeavored to secure the passage of legislation which will withdraw carnotite lands and prevent the location of the same by private individuals, excepting under certain restricted if not prohibitory conditions. The reason given for this is stated to be that the Bureau of Mines, under this favorable condition of monopoly, may produce and manufacture radium for government hospitals. Those familiar with the matter at the present time, must surely be aware that this radium can now be bought at a price cheaper than that at which the government can produce it.

By promising to produce radium at one-third the present market price, a great injustice is done, not only to those who are producing radium, but especially to those expecting to receive relief from the application of radium as a curative agent. A person suffering with cancer, for example, cannot, as a rule, buy radium. Even if he possessed it he could not safely apply it to his ailment.

The medical profession and scientists who are at the present time willing to purchase radium for the treatment of disease and for investigation, are misled by promises of obtaining the radium at a greatly reduced price in the near future.

Without questioning the good faith of the persons who have made and widely advertised such statements at the present time their promise has not been fulfilled. Whether it ever will be fulfilled may be said to be a matter of opinion and for the future to tell. Personally —and I think I am entitled to speak with authority on the subject—I do not think the promise can be fulfilled.

The net result so far has been the discouragement of

investigation and the denial of this curative agent to those who need it. Again, purely as a matter of opinion, I am convinced that this procedure is morally wrong.

Under the present unsettled conditions it is doubtful if not improbable that any group of capitalists would care to risk any money whatsoever in developing the radium industry. And it is certain that should the present plans bear fruit, the radium industry will be absolutely a closed book so far as private enterprise is concerned. Prospecting, mining and development work will be greatly curtailed until those who have promised to produce radium at a greatly decreased cost, are able to make good and show their willingness to distribute their product among those who need it. The investigation among scientific men and institutions will be limited to those who already have a supply of radium because no one is going to buy any material which he believes can be procured, a short time hence, at one-third the market price.

So far as I can ascertain, the promise that radium will be produced at a much lower price, does not carry with it a guarantee that the ultimate buyer will get it at any price whatsoever. The agreement between the government and private parties is, as I understand it, the first 7 grams are to be retained by one man or set of men. At the present rate of 170 mg a year, one must arrive at the conclusion that it will be years before cheap radium will be distributed among physicians and scientists at large.

To those who may have been misled by more or less recent statements, that the ores now mined in Colorado are for the most part exported and thereby lost to our home people, it may be said that the small amount of ore which was mined by prospectors, up to the time the Standard Chemical Company began operation, was sent to Europe. Since that time, as a matter of record, at least 85 per cent of the carnotite ore mined in southwestern Colorado has found its way to Pennsylvania for treatment. In 1913 the exact figure was 83 per cent. The percentage was much greater than this in 1914. It would only be justice to the capitalists and engineers who have put their energies into the solving of this problem to state that the Standard Chemical Company is now producing four-fifths of the world's supply of radium. No mention has been made, I believe, in the Bureau of Mines' publications as to the magnitude, either actual or relative, of this strictly American enterprise.

In the future the radium business will be successful only under one condition—and that is large tonnage. It will always be impossible to maintain an efficient organization of engineers and scientists unless the tonnage is sufficient to pay their salaries.

Standard Chemical Co.,
Canonsburg, Pa.

Heat Insulation.—Heat insulation is as important in refrigerating plants as in boiler plants. In boiler and steam lines the struggle is to keep the heat inside where it belongs. In brine and ammonia lines, in the freezing tank and the cold storage rooms, the struggle is to keep the heat out. Under the suggestive title "Permanent Fortifications" the Armstrong Cork & Insulation Company of Pittsburgh, Pa., has just issued an interesting little bulletin in which illustrations and cost data are given from actual practice showing what can be done in the way of heat insulation by means of the company's nonpareil corkboard, insulating brick and high-pressure covering. Nonpareil high-pressure covering is made of diatomaceous earth and asbestos. It contains no cork whatever. For steam lines, it affords a permanent fortification against heat loss. It is not only an excellent heat insulator, it is also proof against water and steam.

Court of Appeals Decision in the Pyrophoric Alloy Suit

In our issue of April, 1914 (Vol. XII, p. 218), we published the decision of the District Court of the United States, Southern District of New York, in the suit of the Treibacher Chemische Werke versus The Roessler & Hasslacher Chemical Company. The decision was in favor of the complainant, the Welsbach patent in question being held to be valid as a pioneer patent and to have been infringed.

The U. S. Circuit Court of Appeals, Second Circuit (Judges Lacombe, Ward, and Rogers), has recently confirmed this decision. Mr. James Hamilton was counsel for the Treibacher Chemische Werke which won out.

The decision of the Court of Appeals is written by Judge Lacombe. In view of its importance with respect to the legal doctrine of equivalents we give the decision in full:

"The invention relates to manufacture of metallic alloys having pyrophoric action and their application to the purposes of ignition and illumination. The alloy gives forth sparks on being rubbed with a file or otherwise abraded—hence the term 'pyrophoric'. The substance is of conceded commercial utility. Being an alloy it is a compound of two or more metals. Out of fifty-five or more known and classified metals, sixteen are recognized as 'rare-earth metals'; these sixteen are divided into three groups, the cerium group, the terbium group and the ytterbium group. One of the metals in the alloy of the patent must be a rare-earth metal, and by the language of his specifications the patentee states that for the purposes of this invention the presence of the cerium is relied on as essential.

"Therefore, although there may be a mixture of rare-earth metals in the one element of the combination, cerium, or at least a metal of the cerium group, must be present. The testimony shows that an alloy composed solely of rare-earth metals will not produce the pyrophoric alloy desired; the patent indicates this. The presence of one or more of the non-rare-earth metals is essential. The specification states that the rare-earth metal cerium becomes pyrophoric if alloyed with certain other metals, in particular iron. It indicates that with about 30 per cent of iron the alloy attains its maximum of pyrophoric energy; also that the iron can be partially replaced by nickel or cobalt, but if entirely replaced by these the pyrophoric property is considerably diminished.

"The first claim reads: '1. A pyrophoric alloy, containing cerium alloyed with iron; substantially as and for the purposes described.'

"The only other claim is identical except that the iron is stated as being 30 per cent of the compound. As defendant's compound consists of cerium with from 11 to 15 per cent of magnesium, the first claim only is declared upon.

"Judge Hough, discussing the most pertinent references in the prior art, found that the patentee 'taught how certainly and knowingly to produce that' (a compound usefully pyrophoric) 'which had been observed indeed, but not understood.'

"We fully concur in this finding and in the conclusion that this Welsbach patent covers a pioneer invention and is entitled to that liberal application of the doctrine of equivalents which is usually accorded to such patents.

"In defense it is contended that defendant's product, made it is said according to the process set forth in a patent to Huber (No. 967,775, issued August 16, 1910), is not a 'metallic alloy' at all, but a chemical compound. What defendant does is first to make a metallic alloy of cerium and magnesium (in the proportions of about eighty-five to fifteen); this alloy is then subjected to the action of hydrogen in a fire-clay muffle under a temperature of 500 deg. to 600 deg. C. Changes are produced by this hydrogen treatment—the pyrophoric property of the compound is improved, possibly sufficiently to give validity to the Huber patent—and there is a conflict between the experts as to whether the resultant product has become a chemical compound or still remains a metallic alloy saturated with hydrogen. We concur in Judge Hough's finding that the weight of testimony supports the latter conclusion.

"The claim in suit mentions only iron as the non rare-earth metal, but multitudinous authorities support the proposition that, in construing a pioneer patent such as this, 'iron' should be held to mean 'iron or its equivalent'. In the specifications two other metals, nickel and cobalt, are expressly referred to as equivalents and defendant conceded

that a metallic alloy in which these, or even manganese, which like the other three belongs to a group known as the 'heavy' metals, have been substituted for the iron, would infringe.

"But the doctrine of equivalents does not confine a patentee to equivalents which he has expressly referred to. Numerous authorities sustain the proposition that when, as here, a pioneer patentee claims an alloy of one or more rare-earth metals with one or more non-rare-earths metals, he is not restricted to named varieties of either, unless he has himself restricted his claim by something in his specification, as Welsbach did, on the rare-earth side of the combination by the statement that in his alloy cerium is an essential (Winans v. Denmead, 15 How., 330). Welsbach nowhere intimates that iron is essential, on the contrary he stated his invention is the alloy of cerium 'with certain other metals, in particular iron.'

"We are satisfied that the 'equivalency' of other metals with iron is to be found not in their chemical structure, but in their functional efficiency when combined with cerium in a metallic alloy.

"Cases in this circuit (Mattheson v. Campbell, 78 F. R., 910; Richards v. Du Bon, 97 F. R., 96; Panz v. Battle Island Paper Company, 138 F. R., 48) have indicated a qualification of this theory of broad equivalents—a patentee will not be allowed to maintain a claim for more than he has discovered and disclosed. In the first of these cases the claim was for a dyestuff as a new product. The patentee described a special process by which the product was obtained, using therein a specified sulfo-acid; he stated as his discovery, invention and disclosure that 'any sulfo acid of any radical', when treated according to the process described, would produce the dyestuff of the patent. The testimony showed that there were over 100 different substances in the group of 'sulfo acids of any radical' and that only some of them—disulfo-acids, with which along the patentee had experimented—would, when treated according to the process, produce the dyestuff. The complainant contended that whenever a particular sulfo-acid, not tried before, produced the dyestuff his patent would cover it, although it did not cover sulfo-acids, which would not produce the result. We held that he could not thus 'speculate on the equivalents of his claimed invention and thereby oblige the public to resort to experiment in order to determine the scope of the claim of his patent.'

"In the second case above cited the claim was for an improvement in the art of treating tobacco leaves which consisted in 'applying an alkali to the leaves of the growing plant.' Patentee had produced his result of applying a specified alkali to the leaves, but the broad construction of the claim covering *all* alkalis was held void because it would be broader than the invention, as it would cover potash, an alkali which would not accomplish the result, and the patentee had not experimented to discover what alkalis would and what would not do so.

"The case at bar, however, does not come within the principle laid down in these decisions. Of the forty or more non-rare-earth metals it is now shown that there is one of them which will not when alloyed with cerium produce a pyrophoric compound. Some of them will produce a less efficient one than iron does, as the patent indicates, proportions must be varied with different constituents to produce better results, but we are satisfied from the record that (with the exception of metals found in such small quantities that they are known merely in the laboratory and so no one has experimented in combinating them with cerium), each and every non-rare-earth metal is a fair equivalent of iron in the compound of this patent.

"The decree is affirmed with costs."

We comment on the scope of the decision in our editorial columns.

The production of radium, uranium and vanadium in the United States in 1914 was the largest in the history of the country, according to the U. S. Geological Survey. The output amounted to about 4300 tons of ore carrying 87 tons of uranium oxide and 22.4 grams of metallic radium. A little more than 1200 tons of ore containing 28.1 tons of uranium oxide and 7.2 grams of radium, was consigned to Europe; but owing to the war some of it was held in transit. The Standard Chemical Co. and the Radium Company of America produced radium salts during the year, but with the opening of the war nearly all operations were stopped, both at mines and mills. The National Radium Institute, Denver, is now in operation under Bureau of Mines officials, and is producing radium salts.

The Non-Ferrous Metal Market

The month intervening since our last report has witnessed some striking changes in metal prices, the upward trend being most marked in the case of spelter. Copper, tin and lead also experienced a rise culminating during the first few days of Febraury, after which prices receded somewhat. Export demand for spelter, copper and lead has been in evidence and, added to domestic needs, has given the markets a firm tone.

Copper.—During the first three days of February electrolytic copper reached a high price of 14.55@14.60 cents, New York. Since that time the price has fallen off a little to about 14.10@14.20 cents. Business also has slackened and the market is dull.

Tin.—This market reached its high price on February 2, when the New York quotation was 38 cents per lb. Since then it has receded to 36. The rise was without apparent reason, and was regarded as unwarranted.

Lead.—The New York market has been set by the A. S. & R. Co. at 3.80 cents per pound. The St. Louis market has been higher than the usual parity, being quoted at 3.65@3.70 cents. The market is firm though transactions are not on a large scale.

Spelter.—Stocks of this metal, including February production, have been sold out, and considerable business has been done for April and March delivery. Prices have advanced by leaps and bounds, and the high figure may not yet have been reached. New York quotes 7.80@8.30 cents, and St. Louis 8.12½.

Other Metals.—Aluminium is in better demand and the market is stronger at 19@19½ cents, New York. The antimony market is active and large sales are reported both for export and domestic use. Prices range from 17 to 21 cents per lb. Quicksilver has shown an upward tendency, the New York price being $54@$57 per flask of 75 lb. San Francisco quotes $55 per flask.

Mellon Institute of Industrial Research

The new beautiful building of the Mellon Institute of Industrial Research, University of Pittsburgh, will be opened on Friday, February 26, 1915. There will be a reception by the trustees and director in the evening. Professor John J. Abel, of Johns Hopkins University, will deliver the first Mellon lecture under the auspices of the Society for Biological Research of the University of Pittsburgh in the lecture hall of the Mellon Institute on the evening of Saturday, February 27.

The new building which was erected at a cost of $350,000, is the gift of Messrs. A. W. and R. B. Mellon, of Pittsburgh.

The Mellon Institute of Industrial Research stands a monument to the life work of the late Robert Kennedy Duncan. Dr. Raymond Foss Bacon is the director of the Mellon Institute.

The production of manganese ore in the United States in 1914 probably did not exceed, if it equalled, that for 1913 when 4048 tons was the output. Imports have been seriously affected by the war, and during the first nine months of 1914 amounted to only 42,550 tons, or 16 per cent less than for the corresponding period of 1913. Ferromanganese also has fallen off in imports to the extent of 37 per cent, amounting to only 37,420 tons during the first nine months. Three-fourths of our imports have come from Russia and India, and the Russian product has been cut off by reason of the closing of the Bosphorus by the entrance of Turkey into the war. The effect of the shortage in the United States has stimulated interest in domestic deposits, but no important new discoveries have been made.

A Classification of High-Temperature Physical Problems

BY EDWIN F. NORTHRUP

We may assume that temperatures may be produced, artifically, ranging from 2 deg. K. to 4000 deg. K. It is not at all improbable that a temperature exceeding 4000 deg. K. may be produced by electrical means combined with high pressure. But as these methods have not as yet been developed we shall assume that 4000 deg. K. expresses at present the upper limit of temperature producible in the laboratory.

The temperature above which temperatures shall be called "high" or below which they shall be called "low" is very largely arbitrary. In order, however, that definiteness may attach to what follows we shall divide the range of producible temperature into four groups as follows:

Low temperatures... .....0° K. to 233 K. (−273° C. to −40° C.)
Ordinary temperatures.....233° K. to 373° K. (−40° C to 100° C.)
Medium temperatures....373° K. to 1273° K. (100° C. to 1000° C.)
High temperatures....1273° K. to 4000° K. (1000° C. to 3727° C.)

Until within recent years most scientific investigation, with the exception of the study of certain radiation phenomena, has been confined to the range of ordinary temperatures. An examination of the physical and chemical constants, hitherto listed, shows how little the properties of matter outside this range have been studied. This is probably explained by two considerations; first, the means and the apparatus for investigation of the properties of matter below and above ordinary temperatures were undeveloped, and second, information acquired concerning phenomena, only exhibited by matter outside the temperature range in which contact with matter is had in the ordinary affairs of life, formerly possessed, like astrophysics, only an interest purely scientific. Industrial processes were not then, as now, very much dependent upon exact information respecting the laws and properties of matter when outside the range of ordinary temperatures.

The science of the past was engaged in detecting the invariable relations which exist between phenomena when conditions are repeated, in explaining the seeming chaos of nature by codifying the invariable relations of force manifestations, and in discovering and explaining phenomena at ordinary temperatures. This task was made vastly more difficult by the circumstance that in the range of ordinary temperature nature is manifested in her greatest complexity. More phenomena are presented to our senses at ordinary temperatures, and at these temperatures there undoubtedly exist vastly more abundant physical, chemical and life phenomena than in the lower and higher temperature ranges. The growth of our body of science had to take place in a temperature range where the complexity of phenomena was such as to make them most difficult to interpret.

Very low and very high temperature investigations are relatively simple. By passing to the high temperature range we at once eliminate from consideration all such phenomena, as crystallization, magnetism, surface coloring, production of aqueous solutions, the greater part of the phenomena of organic chemistry and a multitude of other familiar physical and chemical manifestations. The science of biology outside the range of ordinary temperatures is non-existent.

As the means and apparatus are now available for quantitative investigation in the lower and higher temperature ranges, a rapid progress should be made in the discovery and interpretation of the phenomena persistent in these ranges, because they are relatively so simple. When nature is studied, simplified, so to speak, we should be able to acquire a better understanding of the increasingly complex phenomena which appear as we bring the lower temperature range up and the higher temperature range down. In the light of our knowledge of nature simplified we shall be better able to interpret her more complex manifestations at ordinary temperatures.

By this new method of scientific investigation at extremes of temperature where nature is relatively easy of interpretation we see before us a line of attack leading to a vast territory of new knowledge. Consider as a concrete case the advance in our understanding of metallic conduction by the work of Onnes at low temperatures. He finds the conductivity, presumably by the atoms being in contact, to be infinite. Again, when others examine at high temperature the metals in their fluid state, their laws of conduction are studied free from the complexities produced by crystallization and past physical history. The temperature-resistance curves of most of them are expressed by straight lines, and, in the main, the resistance is found to get greater as the atoms become more separated by the heat expansion. How much more difficult it would be to arrive at a knowledge of the nature of metallic conduction if we confined ourselves to its study where metals are by chance hard or soft, crystallized or uncrystallized.

The study of matter at *low temperatures* has scientific interest chiefly because it leads to a better knowledge of matter at ordinary temperatures. The knowledge of the laws of matter, physical and chemical, at low temperature does not, however, appear to promise much industrially. This is chiefly due to the fact that the industrial use of temperature, outside the range of ordinary temperatures, has been to bring about new chemical equilibria which remain stable when the product is returned to ordinary temperature. By means of high temperature we produce new chemical products which are stable, and hence useful, at ordinary temperatures. At low temperature, on the other hand, new chemical equilibria are not established and matter taken from ordinary temperature to a very low temperature and again returned to ordinary temperature is, in general, unaltered in its chemical constitution. The new physical aspects assumed by matter at low temperature also, in general, disappear when the temperature is again raised, and the new physical states which exist only at low temperatures have so far, at least, found very little use in the industries.

To those who feel an interest in science chiefly because it gives an understanding of the laws and properties of matter which can be industrially utilized, high-temperature investigations will appeal with more force than low-temperature investigations. The low-temperature range has its able and enthusiastic devotees, but our interest lies in the high-temperature range. The question then presents itself to us: What kinds of investigation at high temperature are possible and useful? To help answer this question we give a classified list of high-temperature problems as these present themselves to our mind. With this list for a guide we shall be in better position to select for investigation problems which experience and judgment indicate are scientifically interesting, industrially useful or both.

High-Temperature Problems

In classifying these the high-temperature range is arbitrarily selected to lie between 1000° C. and the vaporization temperature, at atmospheric pressure, of pure graphite. In what follows respecting the production of temperature only temperatures which are producible by electrical means are considered.

In high-temperature investigation, where all life phenomena are absent, all problems for consideration are included under the general heads: Physical Prob-

lems, Chemical Problems, Electronic or Thermionic Problems and problems in the practical production and measurement of high temperature.

A mere enumeration with occasional comments on all the problems which suggest themselves which are covered by the above four headings would make an article of greater length than is here intended, and only the *physical problems* which suggest themselves are enumerated at this time.

High-Temperature Physical Problems

The physical forces and properties of matter presumably manifested at high temperature and which await investigation are in part included in the list below:

1—*Gravitational Attraction of Matter.*—Is the experimental proof complete, that the gravitational attraction of matter is entirely unchanged when the temperature is raised to the neighborhood of 4000° K.? This is a somewhat difficult but an extremely important question to answer definitely. It is probable that the requisite temperature could be obtained by a chemical reaction, as by thermit.

2—*Surface Tension.*—Does it belong to all matter in the molten state? How does its value in the case of molten metals change with increase in temperature? Is it due to a gravitational, electrical, chemical, or to an un-named force of attraction between molecules or atoms? Surface tension of molten metals could probably be investigated by taking instantaneous photographs of falling globules of the metal and observing the vibration period of the globules.

3—*Molecular Cohesion.*—What are the laws of alteration (or weakening) of molecular cohesion of the highly refractory solid elements and certain of their useful alloys, etc. with great increase in temperature? This is the problem of finding suitable materials for high-speed cutting tools which may be run red hot, and of the tensile strength of wires and cables which must be used under conditions of high temperature. How do the highly refractory metals, W, Mo, and Ta, etc., preserve their elastic properties at high temperature? Is the internal molecular friction increased or lessened at high temperature in materials of this class?

4—*Molecular Adhesion.*—What metals, when in the molten or vapor states, will adhere to or "wet" certain other higher melting point metals in the solid state? Thus, gold wets molybdenum, tin does not wet tungsten. Do metallic liquids or vapors ever wet non-metallic materials? What are the facts and laws regarding the metallic coating of surfaces at medium or high temperatures without the use of aqueous solutions? Inquiries in this line would appear to have commercial importance.

5—*Forces Which Cause Materials to go Into Solution.*—How are materials related as solvents and solutes at various high temperatures? Thus molten copper dissolves copper oxide and also nickel. It does not dissolve molybdenum or tungsten. Why? What are the characteristics or properties of a material or element which which determine its solubility at high temperature in a molten element? This problem is the immense one concerning the formation of alloys and the segregations which occur when the temperature is lowered.

6—*Thermal Expansive Forces.*—What are the curves of volume versus temperature of materials, especially the non-gaseous elements when in the molten or vaporous states? Do liquid metals increase in volume proportionally to the temperature and does their increase in volume maintain the same ratio to their increase in some other physical property, as their electrical resistance? Is there any case where the second property can be deduced from a knowledge of the first? Do the vapors of the easily vaporizable metals obey the ordinary gas laws, as Boyle's law? Will a knowledge of the laws of expansion of molten metals of high vaporization point, as tin, enable the property of expansion to be conveniently used for the accurate measurement of very high temperature?

7—*Specific Heat.*—The specific heat of nearly all substances which are non-gaseous at very high temperature await precise determination. Thus, if the specific heat of tungsten or molybdenum were accurately known up to their melting points an excellent calorimetric method of measuring very high temperature would appear to be easy to develop.

8—*Vapor Tension and Boiling Points.*—The vapor-tension curves of practically all materials, which are solid or liquid in the high-temperature range, await determination. Some of the molten metals, as gold, show considerable evaporation at temperatures considerably under their boiling point, while others, as copper and tin, show comparatively little evaporation until near their boiling point. An accurate determination of the boiling points at atmospheric pressure of most of the metals is much needed. There appear to be good reasons for supposing that accurate determinations of the boiling points of several of the pure metals in the high-temperature range, would furnish a series of "fixed points" of high temperature which would be very useful for calibration purposes.

9—*Fusion Temperatures.*—An accurate determination of the fusion points of many of the pure metals has already been made, but much remains to be done respecting fusion points of the highly refractory metals and certain of the salts. It is especially desirable to determine how the fusion temperature of several of the metals, especially of the precious metals, is influenced by the nature of the vapor or gas in which the fusion of the metal takes place. Thus the fusion temperature of the platinum and platinum rhodium used in thermocouples is much lower in a Co+N atmosphere than in an oxidizing atmosphere. In what atmospheres are the fusion points of the various metals normal and how and to what extent are they affected by other atmospheres?

10—*Viscosities.*—Practically nothing is known in a quantitative way respecting the viscosities of molten salts and molten metals in the high-temperature range. Thus, pure molten iron is said to be quite viscid while pure molten copper is extremely limpid. The velocity of flow of molten metals and molten lavas, etc., largely depend upon the viscosity of the materials.

11—*Compressibility.*—The compressibility of many elements and inorganic compounds with application of pressure and high temperature, is a geophysical as well as a physical problem of importance. This line of investigation is being followed by the Geophysical Laboratory, at Washington. A successful attack upon the problem involves the ability to produce a localized high temperature in the zone of compression and to maintain the surrounding zones cool to permit the compression cylinders to maintain their mechanical strength. All matter at a great depth below the earth's surface is presumably at high temperature and under great pressure. Hence experimental information upon the compressibility of matter at a high temperature gives information regarding the state of the earth's interior. Experiments should begin with a study of the compressibility of the metallic elements when at a high temperature. The resistivities of the metallic elements should be simultaneously studied as undoubtedly there is a close connection between the resistivities of the metals and the closeness of the packing of their atoms or atomic groups.

Query: Is it experimentally possible to bring certain metallic vapors to the condition of being at the critical temperature and at the critical pressure?

12—*Elasticity.*—How is the elasticity, or the ability to maintain or prolong vibration, related to temperature, in the case of those metals and alloys which only fuse at a high temperature? How is the logarithmic decrement of a tungsten wire subjected to rotational vibration related to temperature in the region of high temperature? Or how is its elastic fatigue affected by high temperature? Can all "physical past history" be wiped out by application of high temperature in the case of a material which is not fused by the high temperature? Will increase of temperature which increases molecular separation with a related increase in electrical resistance, in the case of most metals, diminish or increase internal molecular friction? Thus Prof. Malcolm MacLaren has shown experimentally that elevation of temperature greatly reduces magnetic hysteresis. Should we therefore expect that a tuning fork of tungsten would continue to vibrate longer above 1000° C. than it would under this temperature? The experiment could easily be tried for the torsional vibration of tungsten, molybdenum and tantalum wires.

13—*Thermal Conductivity.*—The study of thermal conductivity at high temperature is an extensive field. The inquiry should extend to the relations which thermal conductivity bears to electrical conductivity in the case of elements and alloys. Is there a sudden transition, increase or decrease, as there is in the case of electrical conductivity when a metal changes state? A method has been devised and a piece of apparatus constructed, by the writer, for answering this question.

The investigation of thermal conductivities at high temperatures of inorganic compounds and refractories has a high value for engineers engaged in the construction of high-temperature furnaces. Will these investigations answer the query, whether the transport of heat by conduction is entirely a phenomenon of the passing along of molecular vibrations, or is it due in part or wholly to agitations brought about and passed along by the bombardment of molecules with electrons?

The thermal conductivity of powders determined as a function of their compression should be examined. Even metallic powders when fine grained, as powdered molybdenum, for example, show a high electrical resistance when not under compression and a fairly low resistance when under compression. Is there an analogous relation for the thermal resistance? On account of surface thermal resistance it is probable, that very high thermal insulation might be obtained by concentric metallic cylinders of very thin metal with very small separation between the layers. What would be the thermal conductivity of a stack of alternate layers of thin tin-foil and tissue paper? The writer knows of no data on this subject.

14—*Cooling Curves.*—The determination of cooling curves of the metals, and especially of the alloys, and the relations which they bear to the resistivity curves, is a highly important line of investigation. If the resistivity curves of metals and alloys are definitely related (as there are reasons to suppose they are) to the cooling curves, it is important to determine these relations precisely on account of the light which this information would shed upon the nature of metallic conduction, and because of the practical value to be derived in studying the physical properties of alloys, by determining their resistivities curves by the very simple methods which the writer has devised.

15—*Radiation.*—The radiation from hot bodies offers the most unlimited field of investigation at high temperatures. In addition to the many problems in optical pyrometry, in the study of spectral lines, in the motions of stellar bodies determined by the shifting of their spectral lines, in addition to the problems of absorption of spectral lines by metallic vapors, and the whole question of the synchronism of molecular and atomic vibrations with ether radiations of definite wave lengths, there are a few less commonly stated problems:

(*a*)—What are the laws of metallic reflection from the bright surface of molten metals? Thus the surface of copper at 1600° C. in a reducing atmosphere makes an excellent mirror and gives an image of objects which receive their illumination from the surface of the mirror itself. Is the light in this case polarized at any angle? What in general are the laws of the phenomena?

(*b*)—Do molten salts at very high temperature, which are known to be good conductors of electricity, retain their optical transparency? If they are optically transparent how does their electrical conductivity vary with the frequency when alternating current is used? What is the list of materials which are transparent above 1000° C.? The writer has thought out a method by which this determination could be affected.

(*c*)—As the temperature of a metallic vapor is gradually elevated to near 3700° C. will new spectral lines appear with sufficient suddenness, or will existing lines change in character, so as to permit the temperature to be measured with a direct vision spectroscope? The "cascade attachment" of the Northrup high-temperature furnace offers a perfect means for investigation along many lines of high-temperature radiation.

(*d*)—What are the indices of refraction of molten salts where these are transparent?

(*e*)—What are the coefficients of absorption for light of different wave lengths of the metallic vapors? Much could be learned regarding the vibration frequencies of metallic atoms by the study of the light absorption of metallic vapors.

16—*Osmotic Pressure.*—Can a porous diaphragm be found which molten salts will "wet" at a high temperature? If so, may it not be possible to observe at high temperature the phenomenon of osmotic pressure with molten salts? It is well known that molybdenum is wetted by certain metals, as molten copper and molten aluminium. Could not a diaphragm be made of strongly compressed molybdenum powder and by using this diaphragm to separate an alloy, of say tin and copper on one side and pure tin on the other, to produce the phenomenon of metallic transfusion and metallic osmotic pressure?

17—*Radioactivity.*—Has it been finally and definitely proved that excessively high temperature will not induce either a state of radioactivity or new radiations analogous to X-rays?

18—*Solubility of Gases in Molten and Solid Metals.*—Will a bulb of more or less porous material entirely submerged in a molten metal, as tin above 1000° C., form a gas-tight vessel? What is the solubility, if any, in the different molten metals at high temperature of various kinds of gases? Tungsten and molybdenum heated in a CO+N atmosphere always become crystalline and brittle. Is this due to an absorption and chemical combination with the CO gas? The properties of most metals are much modified when heated in various atmospheres to a high temperature but practically no definite data are available, respecting just what occurs.

19—*Solubility of Metals in Fused Salts.*—Does this ever occur and if so how is the electrical conductivity of the salt affected?

20—*Electrical Conductivity.*—The investigation of electrical conductivity should include:

(*a*)—The E. C. of all the elements which maintain the solid or liquid phase at high temperature. The so called insulators which are elementary substances, as liquid sulphur, should be carefully examined for their electrical conductivity when at high temperature and under such pressure as can be obtained.

(*b*)—E. C. of the metallic elements in the vapor phase at different pressures and different temperatures. Experiments already made by the writer (*Journal* of the Franklin Institute, March, 1915) show that the conductivity depends upon many factors and when measured between a tungsten wire and the walls of a graphite cylinder in which the wire is axially located, is asymmetric; that is the conductivity depends upon the polarity of the wire. Furthermore, different results are obtained when the conductivity is measured with alternating current of different frequencies.

(*c*)—The E. C. of the non-metallic elements in the gaseous phase at high temperature and under high pressure. (The conductivity at low pressures has been extensively investigated.)

(*d*)—The E. C. of several metallic alloys when molten has been examined, but many yet remain.

(*e*)—The E. C. of molten salts for alternating current of different frequencies.

(*f*)—The E. C. for direct current of molten salts under conditions which would reveal an asymmetric conductance, if it exists.

(*g*)—The E. C. at high temperature of standard refractory materials and a determination of the percentage of the conductivity which may be ascribed to hot gases contained in the interstices of the refractories.

(*h*)—A study should be made of the cause of an apparent increase, observed by the writer, in the specific inductive capacity of both hot gases and refractories when attempting to measure the E. C. of these with alternating current of different frequencies.

21—*Electromotive Force.*—The study of the production of e.m.f. chemically in primary cells has been confined for the most part to aqueous solutions at ordinary temperature. There is a large field for investigation at high temperature of the e.m.f. obtainable; (a) between two fused salts separated by a porous partition (b) between a fused salt and a solid, and (c) between two fused metals separated by a porous partition of compressed tungsten powder. May not primary batteries of very considerable e.m.f. and of possible high efficiency result from this study? Should not the matter be reopened of attempting the consumption of carbon in a manner to give rise directly and efficiently to electrical energy? This is one of the great problems which investigations with high temperature are most likely to solve.

The writer has observed that when working above 1200° C. that practically all combinations of two or more materials give rise to electromotive forces—often very troublesome when accurate measurements are being attempted. In fact, because of this, all his measurements of electrical conductance at high temperature of the metals are now made with an alternating-current galvanometer as a detector and alternating current of 25 cycles as the measuring current. The magnitude and the causes of these electromotive forces in the case of certain combinations of typical materials deserve investigation.

22—*Thermoelectromotive Force.*—We have to inquire, (a) What are the thermoelectromotive force curves at high temperature of combinations of solids, (b) of combinations of metallic liquids (as molten tin versus molten lead) (c) of combinations of metallic vapors (as zinc vapor versus cadmium vapor), (d) of the combinations of the solid versus liquid phase of the same metal, (e) of combinations of a solid metal versus another liquid metal, (as W versus molten Sn), (f) of combinations of molten salts.

How little we know about these matters may be determined by consulting any of the standard tables of the physical constants.

23—*Specific Inductive Capacity.*—There are reasons to suppose that a slab of refractory material contained between two slabs of graphite will exhibit the phenomena above 1200° C. of a very leaky condenser having a dielectric of large specific inductive capacity.

24—*Thomson and Peltier Effects.*—As far as the writer knows these phenomena have only been studied at ordinary temperatures.

25—*Mechanical Forces.*—It is always assumed, but as far as the writer knows has never been experimentally proved, that inertia and centrifugal force exist unchanged in matter at all temperatures and obey the same Newtonian laws at 4000° K. as they do at ordinary temperature. Should not this assumption be tested? For example, suppose a large spherical pendulum bob were filled with thermit, would the period remain unaltered while the thermit reacted? The writer is mentally constituted so that he takes nothing for granted regarding which there is an opportunity for obtaining experimental evidence.

26—*Engineering Data.*—There is an unlimited quantity to be obtained of engineering data regarding the physical properties of matter at temperatures exceeding 1200° C. The limitations of the nichrome and platinum-wound laboratory furnaces are largely responsible for the paucity of information respecting the physical properties of matter above 1100° C. or 1200° C.

The above article has been written for the double purpose of assisting the writer in the selection of the problems of high-temperature investigation which he would attack, and to present to the readers of this journal (in an all too inadequate way) the immensity and the fruitfulness of this rapidly enlarging field of investigation. The greatest results can only be expected through interested co-operative effort.

The chemical field and the construction of practical devices have not been considered, though it is probable that the most important developments commercially will come from a study of high-temperature chemistry. It is in the study of high-temperature chemistry, which the writer thinks should be called electrothermics, rather than in the study of high-temperature physical problems that the greater progress commercially may be expected.

Palmer Physical Laboratory,
Princeton, N. J.

The International Engineering Congress announces that the technical success of the Congress is now well assured. From 200 to 250 papers will be presented, representing 18 different countries, so that the Congress will be truly international in character. Membership in the Congress with the privilege of purchasing any or all volumes is open to all interested in engineering work.

Monazite sand in Brazil is found in commercial quantities only on the foreshore at certain points on the coast of the state of Espirito Santo and a few miles north of the town of Prado, in the state of Bahia. The foreshore belongs to the government and leases are granted under the direction of the Minister of Finance. There are at present two active concessions and one passive.

Exports of tin from the Federated Malay States from July 1 to December 31, 1914, amounted to 24,140 tons, as compared with 26,244 tons in the corresponding period of 1913. The total exports of tin for 1914 amounted to 49,042 tons, as compared with 50,128 tons in 1913.

Stratton's Independence milled during December, 1914, 9400 tons of low-grade mine and dump ore. The net profit to the company for the month was $6700.

Leaching a Zinc-Lime Ore with Acids[k]

BY O. C. RALSTON AND A. E. GARTSIDE

In looking over the low-grade and complex ore resources of Utah, it was found that in the two largest mining districts in the State there was a certain type of ore which consisted essentially of calcium and zinc carbonates, more or less associated with some insoluble silica and silicates, the zinc ore being a replacement in limestone.

The following analysis of ore, from the May Day mine, of the Tintic district is representative: Insoluble, 37.4 per cent; CaO, 12.96 per cent; Fe, 4.19 per cent; Al_2O_3, trace (acid soluble); Zn, 15.7 per cent; Pb, 0.55 per cent; Au, 0.24 oz. per ton; Ag, 0.30 per cent; S, 0.65 per cent; CO_2, 19.84 per cent.

An approximate mineralogical analysis calculated from these data, dividing CO_2 between CaO, Zn, and Pb, would be:

	Per Cent
Silica, SiO_2	37.40
Limestone, CaO_3	23.15
Limonite $(Fe_2O_3)_2(H_2O)_3$	6.00
Pyrite, FeS_2	1.20
Calamine, $H_2Zn_2SiO_5$	2.31
Smithsonite, $ZnCO_3$	27.70
Cerussite, $PbCO_3$	0.70
Total per cent	97.46

The undetermined material perhaps includes some alumina, as well as some water of composition, provided part of the smithsonite has been altered to hydrosincite. The above analysis, however, accords fairly well with a qualitative microscopic examination of the ground sample.

There are several other types of oxidized ores of zinc which are much more abundant, but this one is of interest on account of the high percentage of lime and the rather large amount of gold present, the presence of this such gold being somewhat unusual in the Tintic district[1], at least for a zinc ore in limestone.

It is of considerable interest to see whether the zinc could be leached out of the ore with acids or other solvents as a preliminary to cyaniding the gold. To maintain a fairly pure electrolyte for the decomposition of zinc, it is necessary to keep the iron from going into solution. As this particular ore contains such a low percentage of iron it probably would not be difficult to keep the electrolyte reasonably free from iron, while the presence of lime would doubtless be permissible in such a electrolyte because it does not deposit at the decomposition voltages of the zinc salts. However, it can cause trouble in another way, for when currents of high density are used, a sparingly soluble hydrate is formed at the cathode. On account of the low solubility of calcium sulphate, this latter trouble is rarely met in a solution resulting from sulphuric acid leaching.

However, the precipitation problem was left till it was possible to see what could be done with acid leaching; therefore, the purpose of this paper is to report only what seem the most fundamental and important results of these acid leaches, without too much detail regarding connected problems. Other types of leaching, such as alkaline ammonium carbonate, caustic soda, etc., have been tried, but will be reported later.

Leaching with hydrochloric and sulphuric acids was given first consideration for the reason that both can be made very cheaply in the Salt Lake Valley, the one from the salt in the Great Salt Lake, which is present in amounts varying around 26 per cent by weight, and the other from the SO_2 of the smelter gases from four large smelting plants, all within thirty miles of one another and not more than a hundred miles distant from most of the deposits of ore.

Three series of tests were run on the raw ore, crushed to 150 mesh to liberate the zinc minerals as thoroughly as possible, and in lots of 33.33 gms. for each test, with varying amounts of acid and water to make up 100 cc of solution.

The proportions used in these tests were such as to suit the leaching bottles at hand, which were of the ordinary 150-cc type often used for agitation tests in cyaniding. The bottles were placed in an agitator which turned them over completely, end for end, about once every second. All of the acid tests were carried on at room temperature. The pulp after agitation was filtered either with a Buechner funnel or with the alundum filtering dishes now to be had on the market, portions of the filtrate taken for titration and the tailings washed, dried and weighed. The filtrate was analyzed for zinc, lime and iron to check up the analyses for the same elements, on the heads and tailings. The final acidity was also determined in the filtrate.

Description of the Tests.—In the first series of tests identical samples were treated with each acid in amounts insufficient to dissolve the zinc and lime in the lower concentrations, up to amounts of acid sufficient to dissolve all the zinc, lime and iron and still allow residual acid. These are the No. 1 leaches recorded in Table I.

The second series of tests was much the same as the first with the exception that chloride of lime was added to the solutions in anticipation of the solution of the gold by means of the chlorine liberated by the action of acid on the chloride of lime. These leaches are the No. II leaches recorded in Table I. Whether such a method would be advisable in practice is open to question, but it must be remembered that application of cyaniding after acid leaching will require neutralization and probable high consumption of cyanide. Direct application of the old chlorination process, however, could make this a "one-solution" process.

The last series of tests, numbered III in Table I, was run with amounts of acid sufficient to dissolve only about one-fourth of the zinc and lime in each leach, and four of these leaches in succession were applied to the ore. That is, the samples in duplicate, were given a leach with a solution of acid which had seemed by previous tests to be the most advantageous in the dissolving of zinc selectively as compared with the lime, and in amount sufficient to dissolve only a little more than a fourth of the zinc and lime present in the ore. After agitation and filtration the so lution was taken for analysis and the residue leached with the same amount of the same acid, again filtered, dried, weighed and treated in the same way twice again. By this time most of the zinc had been leached out and the tests were discontinued. The object of the series was to compare the two acids in efficiency at different parts of the leach and to see in what order the constituents of the ore went into solution.

The Results. All of the data of the tests are to be found in Table I, just described.

Taking tests I-a to I-f, where hydrochloric acid is solvent, it can be seen that there is sufficient acid in I-a and I-b to dissolve only the zinc in the ore. The result that is of interest from these first two tests is the acid efficiency (amount of acid consumed per unit of zinc extracted) rather than the extraction of the zinc obtained.

The amount of acid necessary to dissolve all the zinc in the samples treated is 5.83 grams. The efficiency of

the acid in these two tests, expressed in "per cent of the acid used up which was used to dissolve zinc," was 46.7 per cent and 51.5 per cent respectively. This shows that in spite of using such a small amount of acid, it was not possible to make all of it go toward dissolving zinc alone, but that instead some of it went to dissolve other soluble constituents of the ore. By testing the leach solution it was found that the rest of the acid dissolve the lime, and almost no iron was dissolved.

Test I-b is known to have suffered a small leak during agitation, causing a loss of acid, but being identical with test III-a, was not repeated. The efficiency of acid in test III-a was 60 per cent.

Test I-c was with more than enough acid to dissolve all the zinc but not quite enough to dissolve in addition all the lime. An 80 per cent extraction of the zinc was obtained, but the figure on efficiency of the acid fell to 45.8 per cent, a result which seems to be low when compared with the next two tests which were run in duplicate.

These two tests, I-d and I-e, were run with just sufficient acid to dissolve all the zinc and lime in the ore, but no iron. An 89.5 per cent extraction of the zinc resulted, with an efficiency of acid expenditure of 48.4 per cent, but it was noticed that a trace of iron was beginning to dissolve.

Finally, test I-f was run with sufficient acid to dissolve all the zinc, lime, and iron. The results show that after twenty-hours of contact a good portion of the iron had not dissolved, as considerable free acid was left in solution.

Summing up this series of tests with hydrochloric acid, we see that it is possible to get an 80 per ecnt extraction of zinc, or better, with about a 50 per cent efficiency of acid to give a solution that is practically free of iron and hence admirably adapted to electrolysis of the solution for obtaining the zinc. This is because lime does not tend to deposit at the voltage necessary for deposition of zinc, and, moreover, because there is no excess acid in this solution.

By increasing the amount of acid applied while the increased extraction of zinc is small, iron tends to go into solution and excess of acid is left, both results being undesirable from the standpoint of electrolytic precipitation. Direct production of metal and regeneration of acid are, of course, the main reasons for wanting to use electrolytic precipitation. The acid efficiencies of this series of tests are shown plotted in Curve I.

In passing it might be well to call atention to the utility of the units used in Curve I. Here, plotted against the various strengths of acid, are to be found the efficiencies of the acid expressed in two different units. For use by the mill man we have expressed the acid efficiency in terms of "lbs. acid used up per lb. zinc, dissolved." For more general application, however, we have also expressed the acid efficiency by giving percentage of the consumed acid which was used in dissolving zinc. This immediately shows what percentage of the acid is used in dissolving materials other than zinc, while the mill man's "lbs. acid per lb. zinc" does not show what efficiency is obtained until his figure is compared with the amount of acid necessary to dissolve 1 lb. zinc where no acid is wasted. This amounts to 1.112 lb. HCl per lb. zinc in the case at hand and 15 lb. of H_2SO_4 per lb. of zinc when sulphuric acid is used. The strengths of acid used are also expressed in two sets of units—one in percentage by weight of acid in the solution and the other in pounds acid per ton of solution used. This method of having both practical and absolute units should prove useful and save transposition of figures.

Tests, I-g to I-l (Curve II) with sulphuric acid, were conducted in exactly the same sequence, the first three being with increasing amounts of acid, insufficient in every case to dissolve all the zinc and lime, while the next two are duplicates with an amount of acid just sufficient to dissolve zinc and lime and the last one with an amount of acid sufficient to dissolve all the zinc, lime, and iron. The iron did not dissolve appreciably until the last test, but here again we find that only a portion of the iron was soluble so that some free acid was left.

The percentages of extraction of the zinc tend to run a few per cent lower than in the case of hydrochloric acid, when compared on a pound for pound basis, but it

must be remembered that the chemical equivalent of a pound of sulphuric acid is less than that of a pound of hydrochloric acid, being roughly $\frac{72}{98}$.

The plot of acid efficiences for H_2SO_4 (Curve II) shows a very smooth curve with a decided maximum at a point where about 6 per cent strength of acid is used, and this maximum attainable efficiency is 63 per cent. A like maximum would seem to be discernible in the case of the tests with hydrochloric acid (Curve I) but not enough points have been determined to place it exactly.

Again, we find it possible to get up to an extraction of 87.5 per cent with an acid efficiency of 47 per cent, while to go further in extraction of the zinc lowers the acid efficiency, fails to increase appreciably the amount of zinc extracted, and takes iron into solution, as well as leaving unconsumed acid to hinder electrolysis.

FIGS. 1 AND 2—EFFICIENCY CURVES

It is an interesting coincidence that if we examine the analysis of the ore we find, with respect to the two soluble constituents, zinc and calcium, the perecentage of zinc is 63 per cent of the sum of the zinc and calcium, while our maximum acid efficiency is likewise at 63 per cent. In other words, at the point of maximum efficiency zinc and lime go into solution in amounts proportionate to the percentages in which they are present in the ore, with no preference in solubility for either constituent. As calcium stands higher than zinc in the electromotive series, this point of non-selective solubility is of considerable interest and its explanation is not exactly clear.

The tests numbered II were made with insufficient acid to dissolve all the zinc; furthermore, varying amounts of chloride of lime were added to supply chlorine for solution of the gold. The zinc extractions were very low, because much of the acid combined with the chloride of lime (which contained 41.6 per cent CaO). On that account the zinc extractions and the efficiencies of expenditure of the acids are of little interest for the time being and only the extractions of gold will be noted. It is seen that in all cases the extractions of the latter were higher in leaches containing hydrochloric acid and bleaching powder than in those leaches where sulphuric acid was used with bleaching powder; however, the amount of bleaching powder used to get these extractions was rather large, varying from 3 to 10 per cent of the weight of the ore. This highest extraction of gold was 75 per cent.

However, tests of this magnitude and under these conditions are not regarded as conclusive, so the inference is that the gold seems to be somewhat readily soluble in solutions containing chlorine. The extraction of the gold will not be further considered in this connection, for the special object of this paper is to call attention to the possible acid efficiency in extracting zinc from an ore so high in lime.

Going back to the maxima in the acid efficiency

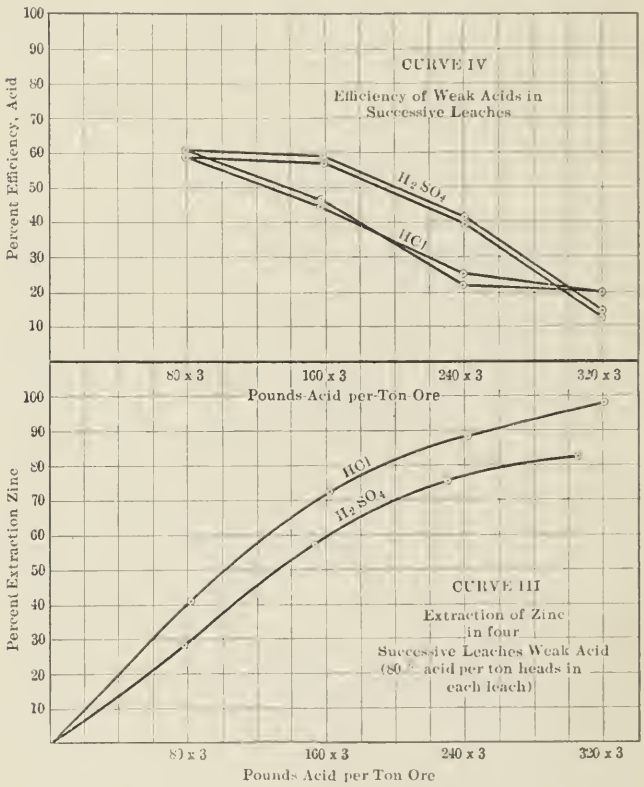

FIG. 3 AND 4—EFFICIENCY AND EXTRACTION CURVES

curves, we find that a certain strength of solution seemed to give the most advantageous conditions for leaching and since not enough acid had been used to extract all the zinc, it was thought advisable to see if successive leaches of acid of this strength would extract all the zinc, and whether they would change in their acid efficiency.

These tests constitute III-a to III-d—III-a and III-b being duplicates with four successive leaches of HCl, and III-c and III-d being duplicates of H_2SO_4 leaches—four in succession in each case.

The results are plotted in curves III to V. Curve III shows the percentages of zinc extracted after each successive leach, there being four points determined on the curve for each acid. Again we find that, pound for pound, hydrochloric acid will extract more zinc than sulphuric acid.

In order to see if a chemical equivalent of H_2SO_4 would dissolve as much as a chemical equivalent of HCl, the units of Curve III were changed from "pounds per ton" to "moles of acid used," and replotted in curves V. We find from this diagram that hydrochloric and sulphuric acid give identical curves and extract exactly the same percentage of zinc, as far as the chemical equivalents go. Though chemically, one is no better than the other, at the same cost per pound, the hydrochloric acid would have the advantage.

Curve III is of interest to the mill man, while Curve V is of interest to the scientist. The fact that the two acids do exactly the same chemical work is very interesting when we remember the different solubilities

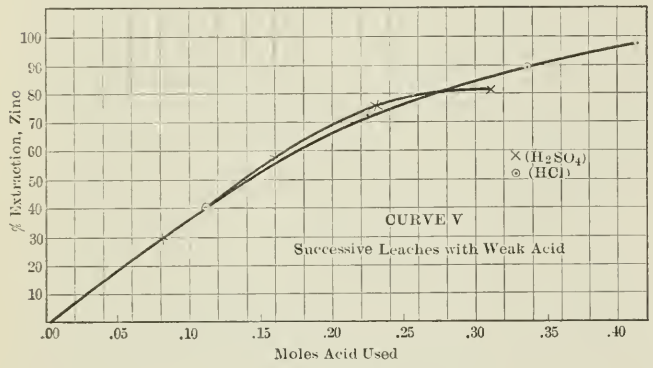

FIG. 5—EFFICIENCY CURVES

of $CaCl_2$ and $CaSO_4$ as well as the other factors which could cause differences in the amount of zinc dissolved in the presence of lime.

The individual efficiencies of each of these same leaches are shown in Curve IV, and rather than take averages of the duplicates, the four tests are plotted separately to show how nearly the duplicates check each other, and to give an idea of the reproducibility of the work. These curves could likewise be replotted with moles of acid as a unit instead of pounds of acid but we know from Curve V that they would fall very close to one another, and hence it is unnecessary.

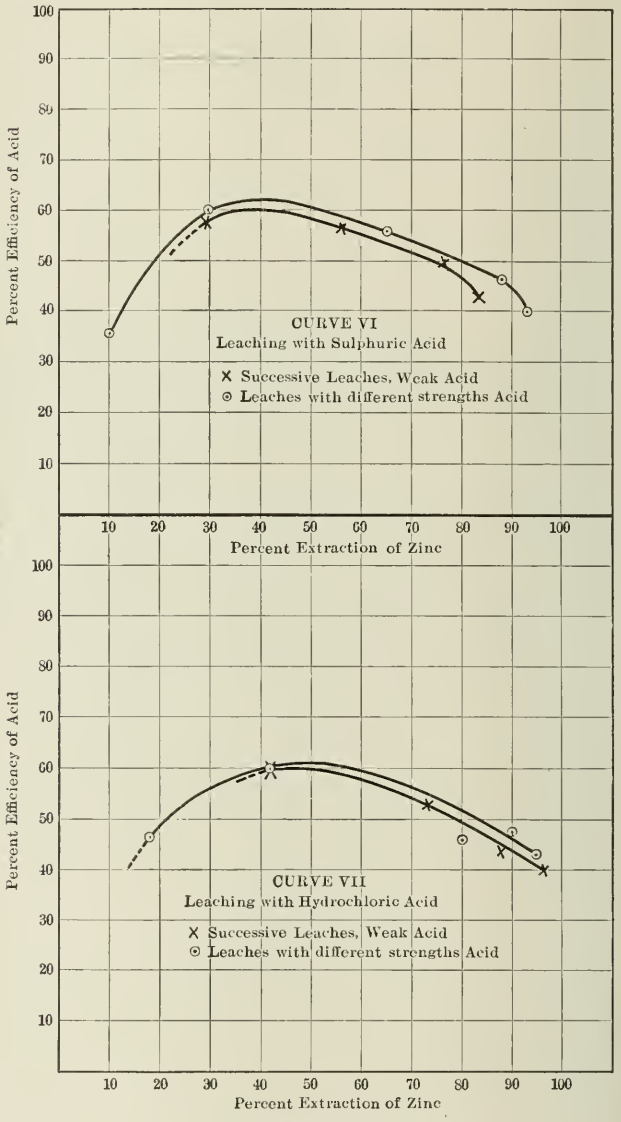
It is interesting in looking over this last series of tests to see that we check our former work of 60 per cent efficiency of acid when about 80 lbs. acid per ton of solution are added but that, as more and more zinc is extracted, the acid efficiency falls off. Suspecting that this drop in efficiency might be due to the same causes that made the higher strengths of acid less efficient, it was thought best to try to compare the tests of Series I with those of Series III by plotting the percentage extraction of the zinc for each experiment against the percentage efficiency of expenditure of the acid.

This is done in Curves VI and VII. The point marked by crosses and the curves drawn through them represent the results of the series of successive leaches with weak acid of the same strength in each leach, while the points marked by circles show the results of the separate tests with different strengths of acid.

The two sets of results seem to give curves that are practically identical. To express this fact we now have to say that as long as you take a certain amount of ore and treat it with a certain amount of acid, you get the same extraction of zinc and use up a certain percentage of the acid usefully, no matter if the acid be applied in one leach or if it is divided into a number of separate leaches.

Furthermore, as one curve is for a constant strength of acid and the other for different dilutions, and the curves are identical, we can say that no matter what the dilution a certain number of pounds of acid can extract only a certain percentage of the zinc and at only a certain percentage efficiency of expenditure of the acid. This result is of fundamental importance for it shows that no further experimenting with various strengths of acid need be tried on this particular ore and whatever the sizes of material employed a similar relation should be found.

Knowing then that we may use acid of any dilution that we please, as long as we get a sufficient quantity in contact with the ore to dissolve the desired quantity of zinc, the considerations which will determine the strength of acid to be used in mill solutions, will depend entirely on the mechanical point of view and different designers will have various opinions as to the best way to take advantage of this fact. So Curve VIII, giving the number of pounds of acid to extract any definite number of pounds of zinc (or to extract any definite percentage of zinc), no matter at what dilution



FIGS. 6 AND 7—EFFICIENCY CURVES

it is applied, will be of the highest practical utility.

Further considerations as to the largest allowable size of crushing of the ore, necessary time of contact, screen analysis, and possibllity of treating slimes and sands separately, as well as the possible influence of temperature on the inner relations and velocity of such leaches have not been investigated thoroughly yet, but the rather unusual turn of events met with in the

course of this series of tests seemed enough to warrant their publication.

Summary: A series of leaches with hydrochloric and sulphuric acids on a zinc lime ore has revealed that if insufficient acid to be added to dissolve the zinc, the efficiency of expenditure of the acid increases to a maximum of 63 per cent (the percentage which zinc forms to the total soluble material) but that further addition of acid to extract further zinc causes the efficiency of expenditure of the acid to fall off more and more to nearly 40 per cent when all the zinc is extracted. These figures are true for both acids.

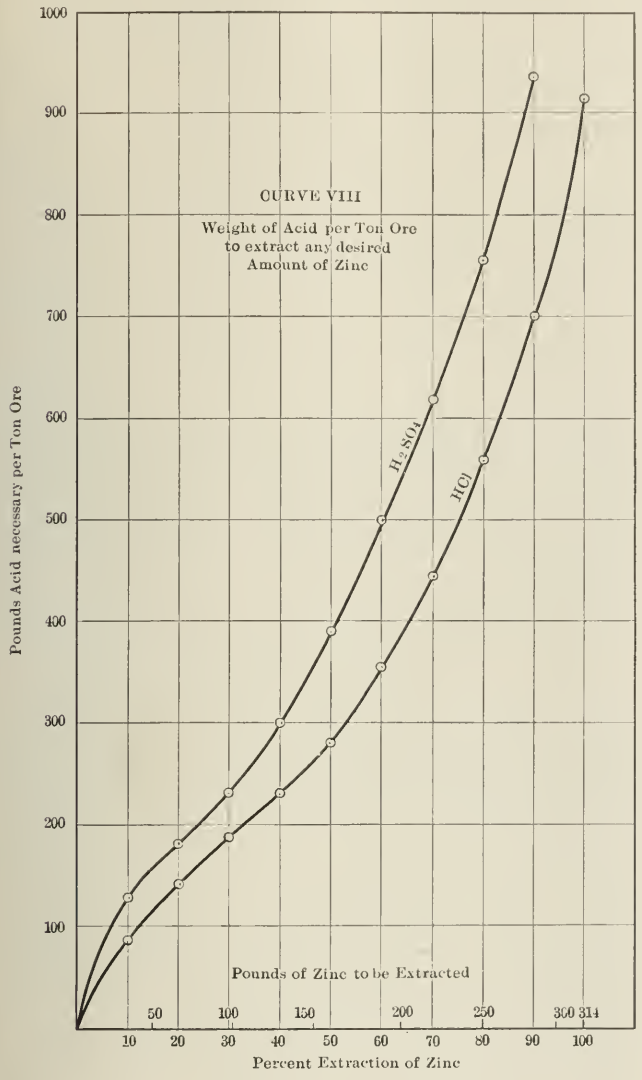


FIG. 8—EXTRACTION CURVES

Chemically, molecule for molecule, the two acids do exactly the same work, a result somewhat surprising in view of the solubility and other relations of the various salts formed. However, the higher chemical equivalent of a pound of hydrochloric acid would give it the commercial advantage of the same cost per pound.

The curious fact has been discovered that no matter at what concentration it is applied, a given amount of acid does the same work; hence the curve of the percentage extraction of zinc plotted against percentage acid efficiency, is the same for all strengths of acid.

It seems possible, by adding chlorine to the leaching solution to get a simultaneous extraction of both zinc and gold, though there is some question as to its desirability.

The Determination of Manganese in Ferrovanadium

BY WILLIAM W. CLARK

The determination of manganese in ferrovanadium is not a serious problem as it can be determined by any one of several different methods, modified to suit the interfering elements present, and as the presence of manganese is not detrimental to steel, in which the majority of the alloy is used, the very accurate determination of it is not a commercial necessity.

Manganese which is added to ferrovanadium in percentages ranging from 0.25 per cent to 10 or 12 per cent has several beneficial properties. It enables the manufacturer to turn out an alloy, which is low in sulphur content, from an ore or oxide which contains considerable of that harmful element. To the user it offers several possibilities. It saves the heat in his steel when the ferrovanadium is added to the ladle, as manganese serves the double purpose of lowering the melting point of the alloy and of increasing its solubility in the molten steel. It saves the addition of a corresponding amount of manganese as ferromanganese, and it also increases the amount of vanadium recovered in the steel. As manganese has a greater heat of combination with oxygen than vanadium and will reduce vanadium oxide to the metal at the temperature of molten steel, it acts as a scavenger, which is more active than vanadium, and thus combines with some of the oxygen contained in the steel as oxides, which would otherwise be combined with and carried out by the vanadium.

The method for the determination of manganese in which the presence of vanadium interferes is the Ford-Williams method. In view of the fact that when a vanadium solution is boiled with strong nitric acid, vanadic acid separates, and also when chlorates are added, the liberation of chloric and chlorous acid precipitates vanadic acid from acid solutions almost completely, and as such a precipitate would be titrated as manganese, the method is useless.

The Volhard method can be used by observing certain precautions, mainly that of keeping the vanadium oxidized to its highest valency. This can be accomplished by using an excess of nitric acid, which will not interfere with the titration in any way, except in the presence of hydrochloric acid, which must be absent. The method in detail is:

The finely powdered alloy is dissolved in nitric-sulphuric acids, evaporated to small bulk, a few cc of concentrated nitric acid added, the solution boiled to remove all nitrous fumes, diluted, and almost neutralized with sodium carbonate solution. An excess of zinc oxide emulsion is then added and the solution is boiled for one minute. An aliquot portion can then be filtered off, over a dry paper and titrated, but it has been found that the presence of the precipitate in the solution is rather beneficial than harmful. The precipitate of vanadium and iron, which settles rapidly, envelops and carries down the slow-settling manganic oxide, thus saving time and making the end point sharper. There is a small correction factor to be determined, as it has been found that the theoretical factor will not give the actual content. This factor is determined by making a synthetic standard ferrovanadium from alloy free from manganese and a weighed portion of the Bureau of Standards manganese ore. Following are results obtained by this method:

The method using lead peroxide as an oxidizing agent could also be used but it requires a filtration which is objectionable, and it also demands the absence of sulphuric and hydrochloric acids, which are hard to remove, and the alloy breaks up with difficulty in nitric acid.

Manganese present Per cent	Manganese recovered Per cent

	9.94

The method worked out by Dr. Cain using basic carbonates and oxides to precipitate the vanadium, free from manganese, and the manganese determined in the filtrate, can also be used and very good results are obtained, but it also has to be filtered. A slight modification of this method gives good results, and consists in reducing the vanadium by evaporation with hydrochloric acid, thus having the iron oxidized and the vanadium reduced, and then precipitating the iron and vanadium together, and determining the manganese in the filtrate.

The method which has been found to be the most accurate on all percentages of manganese found in commercial alloys is the persulphate method with the subsequent titration of the permanganic acid by sodium arsenite solution, which does not reduce the vanadium as does ferrous sulphate. The titration of the permanganic acid is always to be preferred instead of the comparison of the color with a standard of approximately the same percentage. The standard is not always available, and the yellow of the vanadium is not standard as different acidities give different tones, and what is of more importance, the titration is more accurate and can be done more quickly.

The method in detail is as follows:

0.2 gram of finely powdered alloy is dissolved in 10 cc of a nitric-sulphuric acid mixture (200 cc H_2SO_4, 200 cc HNO_3, and 400 cc H_2O) with the addition of a little hydrofluoric acid, if the alloy is refractory to these acids. The solution is vigorously boiled, diluted to 100 cc, 10 cc of a silver nitrate solution added (1.25 grams per liter) and an excess of solid ammonium persulphate. The solution is brought to a boil and cooled at once in cold water, a few drops of saturated solution of salt is added, and the manganese titrated to the disappearance of the last trace of pink. The operator can catch this point very exactly after a few trials, as the end point is very sharp and can be caught with one drop of the solution. In case the manganese content is above 5 per cent, the solution is diluted and an aliquot portion taken before adding the silver and persulphate. The general idea for this method is that it is not applicable for percentages above 1.5 or 2 per cent, but after using it for a number of years it has been found to be as accurate as any of the other methods on materials containing as high as 15 per cent manganese. The only precautions to be observed are that there must not be more than 0.01 gram manganese for each 100 cc of solution; chlorides must be absent and the acidity must not be too high. Larger amounts of manganese than above mentioned will cause a precipitate of manganic oxide in the solution, which does not titrate theoretically. Even with the above amount in case the acidity is too low, there is sometimes a precipitate, but it can generally be cleared up with a few drops of nitric acid.

The arsenite solution is made by dissolving sodium arsenite in water and standardizing against a standard ferrovanadium made from manganese free alloy and the Bureau of Standards manganese ore. The solution most used is standardized so that 1 cc will equal 0.05 per cent manganese on a 0.2-gram sample. The addition of the salt solution is also very necessary as it combines with the silver, rendering it quiescent. Otherwise the silver still being active as a catalytic agent, slowly reoxidizes the manganese during the titration, and while this is of no importance on a low value, on a high one, in view of the fact that the error so introduced is multiplied in accordance with the aliquot portion, it is considerable. The method is very rapid, taking only about fifteen minutes when the aliquot portion is not required, and then only a few minutes longer. Following are results obtained from this method, showing that it is possible to obtain concordant results commercially:

Manganese present Per cent	Manganese recovered Per cent
0.50	0.49
	0.48
	0.50
	0.51
	0.50
1.25	1.23
	1.24
	1.27
	1.22
	1.24
5.00	4.92
	4.94
	4.96
	4.94
10.00	9.90
	9.88
	9.92
	9.92
	9.90
15.00	14.96
	15.04
	15.06
	14.95

The determinations for the 0.50, 1.25, 5.00 and 10.00 were titrated with a solution standardized against the 0.50 per cent, while the 15 per cent was standardized against a 15.00 alloy. By using weighed burettes closer results might be obtained, but the above are close enough for any commercial purposes.

Seymour Mfg. Co.,
Seymour, Conn.

The Purification of Boiler Feed Water

BY EVERARD BROWN

It is a well-known fact that the use of bad water for boiler feed purposes is not conducive to satisfactory and economical steam plant operation. It is also true that natural waters are hardly ever pure, no matter what their sources may be, and instances are indeed rare where the water is fit to be used for making steam without its receiving treatment of some kind either before or after its introduction into the boiler. Furthermore, there is a vast difference in the character of different waters, consequently each case must be studied and worked out by itself and the proper remedy prescribed. It is evident, therefore, that the elimination of impurities in the boiler-feed water and making it suitable for steaming purposes is one of the most difficult problems that confronts the engineer.

The various impurities in all waters may be divided into two general classes; namely, insoluble impurities, which can be removed by sedimentation or by filtration; and soluble impurities, which cannot be removed unless they are first thrown into suspension and then taken out by sedimentation or by filtration. While the insoluble or suspended impurities are a factor in considering the suitability of a water for boiler-feed purposes, nevertheless, they are of minor importance and can be taken out so easily that they need not here be further considered.

The most common of the soluble impurities, or those held in solution, are the following:

Magnesium sulphate, which is quite common in many waters and is extremely soluble. By itself it will not form scale, but it is easily broken up by lime salts from which scale is formed.

Calcium sulphate, also quite common in all natural

water supplies and which forms the hardest boiler scale. Furthermore, this salt will act as a cement, causing a hard scale formation with salts which ordinarily would form only a soft scale or sludge.

Calcium carbonate, which is only slightly soluble in pure water, but in the presence of carbonic acid dissolves in the water, forming bicarbonate of lime, which is soluble. Alone, however, bicarbonate of lime will not make a hard scale, but when present with other substances, which cement it, a hard scale is apt to result.

Magnesium carbonate is more soluble than calcium carbonate. It is usually found in water as bicarbonate of magnesia and has nearly all the characteristics of calcium bicarbonate.

Calcium chloride, which is very soluble and sometimes found in natural waters. In the absence of other scale-forming salts it is not injurious unless highly concentrated. After concentration in the boiler, however, it becomes dissociated and liberates hydrochloric acid, which, of course, is highly corrosive.

Magnesium chloride, a very objectionable salt because it both forms a scale and liberates hydrochloric acid.

Calcium nitrate, having practically the same characteristics as calcium chloride. Waters containing this salt are, however, comparatively rare.

Magnesium nitrate, usually present in only very small quantities and characteristically similar to magnesium chloride.

Sulphates of iron and alumina may be found in waters contaminated with the waste from galvanizing works or with mine drainage and, because of their dissociation by heat, sulphuric acid is given off and the iron or alumina precipitated as scale or sludge. These substances are very injurious in a boiler and cause corrosion the same as free sulphuric acid. The oxides of iron and alumina, on the other hand, while usually present in small quantities in nearly all waters, have but a slight bearing on scale formation.

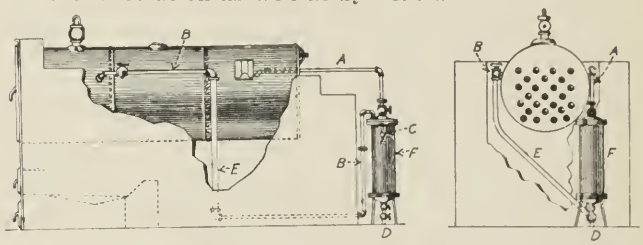
Sodium salts, that is, the sulphates, carbonates, nitrates and chlorides, are all neutral, do not form scale and are non-corrosive, consequently they are not objectionable unless present in large quantities. Silica may also be found in nearly all waters and, while it is a scale-forming substance, yet it is present only in such small quantities that it usually need not be considered.

In addition to all of the foregoing there is always some free carbonic acid in all natural, or raw, water which, of course, promotes corrosion in the boiler. This acid also holds in solution the calcium and magnesium carbonates. Also, if the water contains drainage from mines or galvanizing plants, there is sulphuric acid present in its free state which is extremely objectionable because it attacks the metal in the boiler immediately. This action forms iron sulphate which the heat in the boiler decomposes, resulting again in free sulphuric acid and iron hydrate. The liberated acid again attacks the metal and so goes through repeated cycles indefinitely. Since this acid is not volatile, its amount in the boiler is naturally increased continually by the quantity introduced with the feed water, so that it can easily be seen how the corrosive action multiplies in intensity and in direct ratio, as it were, with the concentration in the boiler.

The soluble-scale forming matter may also be divided into two general classes, those causing temporary hardness of the water and those causing permanent hardness. The former consists of the carbonates of lime, magnesia and iron. Their precipitation begins at temperatures approaching 212 deg. Fahr. and they can be entirely removed by boiling the water at atmospheric pressure for a short time. Permanent hardness is due to the sulphates, chlorides, and nitrates of lime, magnesia and iron which will not be precipitated at temperatures below the boiling point, consequently their removal together with that of the acids constitutes the real problem in water purification.

From the fact that a natural, or raw, water can contain such a large variety of impurities in varying quantities, it is evident that the problem is rather complicated and that each specific case must receive individual attention if the results are to be satisfactory. It should also be remembered that the characteristics of the impurities change under the different pressures and temperatures in the boiler and that their scale-forming properties are largely interdependent. Furthermore, the amount of scale formed does not always bear a direct relation to the amount of impurities in the feed water, but depends on the type of boiler and the rate at which it is operated as well as upon the nature of the impurities. Concentration in the boiler is another factor that enters into the question, since none but volatile matter passes out with the steam, consequently the non-volatile impurities gradually accumulate, forming varying quantitative relations with each other.

Although the scale formed in a boiler is the direct result of impurities in the water, yet an analysis of this scale is of practically no value in determining the character of the water from which the scale was deposited because of the fact that the scale is the precipitation resulting from reactions between some of the substances in solution as well as by heat and concentration.



APPARATUS FOR SODA ASH TREATMENT

Therefore, the original character of the impurities in the water is not always apparent in the scale.

In order to decide on the suitability of a water, or on its treatment for boiler feed purposes, it is essential that a careful and accurate analysis of it be made. This should be done by a chemist who makes a specialty of such analyses and who is thoroughly familiar with the characteristics of the water in relation to boiler operation. Unfortunately, however, this is not always done; or the remedy prescribed as a result of such analysis is not carried out. This is evidenced by the fact that scale is still prevalent in many boilers and that the manufacturers of tube cleaners, etc., are still busy making mechanical scale removers. Moreover, there are many compounds as well as mechanical contrivances on the market that are guaranteed (?) to prevent scale formation in the boiler, no matter what kind of water is used. Some of these may be efficacious under certain conditions and with certain waters, but as a general cure-all they are an absolute failure.

Use of Boiler Compounds

One quite prevalent method of preventing scale, or rather trying to, is by the use of boiler compounds, some of which act chemically and others mechanically. Kerosene and crude oil are also sometimes used, but to a much less extent. Graphite is the most common material which acts mechanically and its purpose is to give the interior of the boiler a thin coating which will prevent the adherence of the scale-forming matter to the shell and tubes. It seems, however, that its efficacy under all conditions and for all kinds of water is a matter for honest debate. The compounds which act chemi-

cally usually consist of sodium carbonate in combination with some organic acid such as acetic or tannic.

While it is true that in certain specific instances the use of a boiler compound has prevented, or at least reduced, the formation of scale, nevertheless, in order to obtain such results it is essential that the quality and quantity of the compound should be specially adapted to the particular water in which it is used. This makes it extremely difficult to use a compound successfully because of the variable quality of feed waters and the large variation in the amount of water fed into the boiler. As a rule, however, boiler compounds are quite effective in overcoming corrosion because they are usually alkaline in nature and, therefore, neutralize the acids. On the other hand, extreme care should be exercised in using a compound for this purpose because many of them contain corroding agents and consequently are in themselves the cause of corrosion.

Aside from acting as a neutralizing agent for acids, the only function of a compound is to change the nature of the precipitate from one which adheres to the surfaces of the boiler to one which will be carried in suspension in the water. The result is a muddy, insoluble mass made up from the impurities already in the water plus the ingredients in the compound itself. This naturally increases the density of the water and consequently its boiling point is raised because of the fact that the soluble impurities are constantly increased by the concentration resulting from the evaporation of only pure water. This action makes of the boiler simply a catch-all or accumulator for the foreign matter. Furthermore, this accumulation of sludge cannot be entirely removed by blowing off, therefore frequent washing out becomes a necessity. In brief, it may be said that the use of boiler compounds is an attack on the result rather than on the cause and as such should only be followed when no better means of treating the water is practicable.

Soda Ash Treatment Within the Boiler

There is another method of treating boiler feed water on the market which is similar in principle to the use of boiler compounds in that the water is treated after its introduction into the boiler. This system goes a step further, however, and employs a filter to remove from the boiler water all the impurities held in suspension. In other words, it is a combination of chemical treatment and mechanical filtration. Reference to Figs. 1 and 2 will show the principle by which this is accomplished.

Soda ash is first introduced into the boiler in sufficient quantities to throw into suspension all the soluble impurities contained in the water. The water containing this suspended foreign matter is then drawn off through the pipe A and carried down through the center of the filter F which has a collecting space at the bottom. It is then forced upward through a crushed granite filtering medium and returned to the boiler as pure water through the pipes B and E. The Pipe E, which acts as a circulating pipe also, is considerably larger than any of the other connections and is so located in the boiler furnace as to be exposed to the greatest heat, the idea being that the circulation set up in this manner will cause sufficient suction through the apparatus to draw off the suspended matter from all parts of the boiler. To clean the filter the blow-off valves D are opened and the valve on the "draw-off" pipe A is closed. This releases the steam pressure through the return pipes B and E and reverses the flow through the filter, thus removing the collected sludge, etc., from the filter. C is a small vent to free the filter from steam after blowing out. The location of the connections of pipes A and B to the boiler are of no special importance except that they must be below the flue level so as to be entirely submerged.

It would seem that a considerable loss of heat would be entailed by the use of this system of water purification, both from radiation and from the loss of the heated water blown out through the blow-off valves. In fact, a loss by radiation is practically admitted by the manufacturers of the apparatus because the assertion is made that a lower temperature in the filter materially assists precipitation, which is completely effected in the upward movement of the water through the filtering medium. That a loss results from blowing out some of the heated water every time the filter is cleaned is, of course, self evident. Furthermore, while this apparatus, if it performs the functions intended, will prevent concentration in the boiler, yet the same objections to it might be raised that apply to the use of boiler compounds; namely, it is not good practice to do the purifying within the boiler itself because of its interference with the business of making steam. Any advantages it might have lie in its cheapness, small floor space required, low operating cost, etc.

A Physiochemical Action

Perhaps the most remarkable and startling novelty in the way of a feed water purifier is what is called a "Luminator." It consists simply of an aluminum plate of specific dimensions and having corrugations thereon of a particular size, both of which are determined by the character of the water to be treated. The treatment is merely allowing the water to run over this plate. It seems that a current of electricity is induced by the passage of the water at certain speeds over the plate and, the water being negative and the plate positive, ionization of the salts takes place. These do not take a crystalline form but become amorphous. It seems there is also another action which takes place; namely, aluminum is by friction and electrical action abraded from the surface of the plate as a colloid, which, after a period of time, also undergoes a change in the water. These remarkable changes are all brought about without the aid of chemicals of any kind, the whole process being called purely "physiochemical."

Professor Donnon at the Liverpool University, England, has investigated this process, it seems, and has found that aluminum hydroxide was not present to any appreciable extent in the water treated by this method; but he did find that the aluminum was in a collodial form mixed with hydroxide and remained so for several days after treatment. Reports further seem to indicate that the best results are obtained when the so-called "luminator" is facing either north or south and is exposed to direct light! Also that if shut in completely from light and air it becomes almost inoperative. The professor assumes that the earth's magnetism has some effect on the operation of the plate and that if its plane is set so that the earth's magnetic field crosses it there will be produced a small electromotive force at right angles to the grooves of the plate as the water flows down, resulting in a slight electrolytic action and thus precipitating aluminum hydroxide in the solution. He also says that the local electricity, together with a certain amount of chemical action, due to the heterogeneous nature of the metal, are sufficient to explain the surprising and hitherto unknown disintegration of the aluminum. That this explanation is quite clear is more than doubtful.

The foregoing would indicate that boiler troubles resulting from scale formation could be overcome by the simple expedient of installing an aluminum plate and passing the feed water over it. There must be, however, certain limitations to the efficacy of this method of water purification. For example, water containing ferrous sulphate, or large quantities of iron in any form, are

not susceptible to such treatment because of the continual deposit of iron on the plate.

Likewise, any acid in the water will not be neutralized, such water requiring a preliminary treatment by passing it over marble or chalk in order to get the desired result. Furthermore, if the "luminator" is at some distance from the boiler it is necessary that the water mains, etc., be coated with a non-conducting composition, such as bituminous varnish, and that the water reach the boiler as soon after treatment as possible. The statement is also made that where the apparatus is used continuously night and day it is advisable to give it a rest of one day per week, otherwise the plate may become "polarized." It is rather difficult to reconcile this statement with the one stating that the plate must be exposed to light to be effective. If the latter is true how can it be used both day and night?

Assuming that this aluminum plate will do the things that are claimed for it, the question is: What becomes of the various impurities contained in the water? In reply to this we are told that the various salts in the raw water before and after treatment show, upon analysis, the same chemical composition; that the sulphates and carbonates of calcium, as well as the magnesium salts, remain as before; and that only a physical change takes place. In a boiler this change is supposed to take place immediately, thus preventing the salts from again going back from the amorphous to the crystalline form, consequently they are deposited as a powder.

This supposed action of the "luminator" and the consequent results obtained therefrom may, perhaps, be quite clear to the inventors, but to the writer it certainly savors of mystery and magic. In other words, this "luminous" treatment of water is not very illuminating and the claims supporting it are far from convincing. At all events there will no doubt be considerable "missionary" work required before it receives anything but the most skeptical consideration.

Water Heater-Purifiers

One of the common methods of attacking the problem of scale formation in the boiler is by pre-heating the feed water. This method is based on the well-known fact that raising the temperature of water reduces the solubility of some of the salts in solution. The apparatus used for this purpose is the "feed-water heater and purifier," and is designed to receive the deposition of the scale-forming substance instead of letting them enter the boiler itself. That it will fulfill this purpose to some extent is unquestionably true, but whether it completely solves the problem or not is rather doubtful.

There are two kinds of heater-purifiers on the market, both of which are supposed to intercept the impurities in the water. One is the open or exhaust steam heater into which only exhaust or low-pressure steam is introduced to heat the water, and the other is the closed or live-steam heater in which steam at boiler pressure is used. In the first, of course, the temperature of the water cannot be raised to more than 212 deg. Fahr., the boiling point of water at atmospheric pressure. It is also obvious that in this type of heater only the temporary hardness of the water will be effected and that only partially, because precipitation is a gradual rather than an instantaneous process and the length of time the water is usually allowed to remain in the heater is not sufficient to make the precipitation complete. To overcome this difficulty the size of the apparatus has lately been increased so as to allow the water to remain longer; and in some instances softening reagents have been introduced and a filtering device attached. These steps taken by the manufacturers are an indication that the old type of open, exhaust heater-purifier does not fully meet the requirements.

The closed type, or live-steam apparatus, on the other hand, will remove practically all of the temporary hardness but not all of the permanent hardness. While it carries practically the same pressure and temperature as the boiler, yet to precipitate calcium sulphate, for example, a certain amount of concentration is necessary in spite of the general assumption that this salt is insoluble at temperatures above 300 deg. Fahr.

The real function of a heater is to heat the feed water and as such both types are very successful. As a purifier, however, it does not quite come up to requirements, although it must be given credit for doing some good. In the same sense that a feed-water heater is also a purifier so might the boiler be called a purifier because scale deposits in both. Aside from heating the water, the advantage in the heater is that this deposit is more easily removed than from the boiler, provided, however, it entirely purifies the water so there will be no deposition at all in the boiler.

Chemical Water Softening Systems

Any method or apparatus for softening and purifying water in a satisfactory manner must be such that the acid contained will either be eliminated or neutralized; the permanent hardness removed and any remaining scale-forming substances reduced to a negligible quantity. It must also produce a clear effluent. If these results are not obtained, then the method employed is either wrong in theory or application, or the apparatus is faulty in design or operation or both. Of course, to properly treat water is a rather delicate process, more so perhaps than might be generally believed. This is because of the small relation the amount of impurities, which have to be removed, bears to the volume of water to be treated. Therefore, to get results, an accurate analysis of the water is of prime importance for determining the treatment and the apparatus required.

Without doubt the most satisfactory and efficient manner of treating feed water is by means of proper reagents in exact quantities to react with the impurities, followed by the complete clarification of the water by sedimentation and filtration. The apparatus on the market that operates on this principle is commonly called a "water softening and purifying system." There are two types of this apparatus, one called the continuous and the other called the intermittent. Either one will produce good results if given proper attention.

In the continuous system the reagents are introduced by proportional feed devices, usually actuated by the water entering the system. The water enters either at the top or bottom and flows out by displacement at the same rate at which it enters. An adjustment must, therefore, be made in the quantity of reagents introduced in order to meet every variation or change in the water. Unless this matter of adjustment is watched carefully there probably will be times when the water is overtreated and other times when it is undertreated.

In the intermittent type, on the other hand, the water is always treated in measured quantities, and the exact quantities of reagents required are weighed out; therefore, any water can be treated most accurately, no matter how it may vary in quality or quantity. But, as compared with the continuous system, it requires much more ground area, more expansive foundations, and possibly a little more labor to operate.

However, it is not the intention to weigh the advantages, or otherwise, of the one system against those of the other, because, as said before, if properly attended to, either one will give results, as attested by the fact that there are a great many of both kinds not only in use but also are being sold at the present time.

As a general rule the reduction of the scale-forming impurities to 5 grains per United States gallon and the

elimination of the acids is considered good practice. There are, however, cases where it has been found necessary to reduce the scale-forming substances to less than 3 grains to prevent scale, and others where good results are obtained with as high as 6 to 7 grains. It is impossible, of course, to remove all of the substances, as calcium carbonate and magnesium hydrate are slightly soluble at all times. Nor is it possible to take out any sodium salts except by distillation, because they are all soluble and no chemical treatment will throw them into suspension. In properly treated water, however, they do no harm to the boiler as they are neutral, non-corrosive, and non-scaling.

The reagents commonly used in these water-softening systems are lime and soda ash, although other substances are sometimes used, depending upon the nature of the water. The cost of purifying will, of course, depend upon the amount of reagents required, for it is readily understood that it will require more chemicals to remove 30 grains of some impurity than it will to remove 10 grains. Almost any expense, however, incidental to the proper softening and purifying of water for boiler feed purposes is more than offset by the savings that result.

In conclusion it might be observed that the limit of possible economy is much more distant in the boiler house than in the engine room and that the first essential in economy of boiler operation is that the water should be of a quality which will permit of the utilization of the greatest number of heat units in the fuel, at a minimum cost of boiler maintenance. In many steam plants may be found the most improved design of boilers, with mechanical stokers, stack dampers, feed-water regulators, feed-water heaters or economizers, and no doubt the most economical prime mover obtainable in the engine room; but the matter of pure water is often totally neglected.

Electric Smoke and Fume Precipitation Before the American Institute of Electrical Engineers

The morning session of Friday, February 19, 1915, of the Midwinter Convention of the American Institute of Electrical Engineers was devoted to a symposium of papers on electrostatic fume and smoke precipitation. The large lecture hall of the United Engineering Societies Building was filled. Many members of the American Institute of Mining Engineers were present, following a cordial invitation extended to them. President P. M. Lincoln of the American Institute of Electrical Engineers presided.

The first paper was presented by Dr. Frederick G. Cottrell who gave a very full and detailed historical sketch of electrostatic fume precipitation, starting with a German text book note of 1824, but dealing naturally in greater detail with the work of Sir Oliver Lodge, and then sketching his work which led Cottrell, jointly with O'Neill, Heller and Miller to the formation of the Research Corporation (see our February issue, pages 81 to 84). Work along similar lines, under the direction of the late Robert Kennedy Duncan, of the Mellon Institute, was also noted and Dr. Cottrell was glad to state that a method of coöperation between the Research Corporation and the Mellon Institute had been effected.

The electrostatic precipitation process is naturally suited to solve two problems: first, the precipitation of man-made fumes (smelter fumes, smoke from boiler furnaces and the like), and second, the precipitation of fog, in the open atmosphere. Sir Oliver Lodge had been specially interested in the second problem. Dr. Cottrell had so far worked only on the first problem, as there was enough trouble to be overcome in its special field and the second problem is better attacked after the first one is solved. Now the San Francisco Exposition seems to offer possibilities of experiments on the second problem and shipping interests have become quite interested in the possibility of using Cottrell apparatus in front of a vessel to dispel fog and prevent accidents.

The second paper of the session was presented by Dr. W. W. Strong, of the Mellon Institute of Industrial Research, on "the theory of the removal of suspended matter from fluids."

The frictional resistance of a small particle moving through a fluid is given by the law of Stokes. Knowing the density and size of the particles and the coefficient of viscosity of the medium, the amount of energy required to remove suspended matter from fluids can be calculated. From the formulas the relative efficiencies of the different methods used to remove suspended matter from gases can be obtained. From these formulas the electrical method is shown to be especially adapted to fine suspended particles or to a mixture of gases that can be selectively ionized. In a practical case of electrical precipitation of smoke it is shown that approximately 4 per cent of the energy of the corona discharge is actually expended in the process of precipitation.

The manner of the distribution of the energy of the corona discharge is discussed. The nature of the corona ionization and the "corona" rays is also briefly described.

The application of the theory of electrical precipitation is given so that it is possible to determine the best working conditions for precipitating a given kind of suspended matter from a given fluid. The theory also indicates the limits of usefulness of the method of electrical precipitation.

Dr. Strong showed at the conclusion of his paper a number of lantern slides and moving pictures.

Professor A. F. Nesbit, of the University of Pittsburgh, followed with a paper on "the theoretical and experimental consideration of electrical precipitation," also illustrated by lantern slides.

Mr. Linn Bradley presented the last paper of the session on "practical applications of electrical precipitation and progress of the Research Corporation."

The technical and financial progress made by the Research Corporation since its organization in 1912 is given, and several plants are described. Voltages, electrode spacings, power consumption, etc., are given for several installations. Mention is made of a number of improvements in the electrical apparatus and means for its control. Progress has been made towards standardization of apparatus for this work.

The paper is illustrated with reproductions from photographs of installations in various stages of operation. Curves and charts show the peculiar character of the circuit, the method of obtaining data to be used in designing treaters and of conducting tests. Alternating current of 250,000 volts has been rectified and used for precipitating particles from gases. Fumes have been separated into fractions by means of temperature control and the electric process.

A selected bibliography is included. The statement is made that within three years time the original capital of $10,100 has been paid back to the stockholders, and that a fund of over $150,000 has been accumulated from the corporation's work, to be used for scientific research.

After the conclusion of the paper Mr. Bradley showed lantern slides and moving pictures of Cottrell plants in actual practice and finally demonstrated experimentally the Cottrell process for fume precipitation. The demonstration was very successful, the smoke being instantaneously stopped by closing the circuit of the Cottrell apparatus, and appearing again quickly when the circuit was opened.

In the discussions which followed Messrs. Franklin, Bradley, Dushman, Nesbit and Job participated. Of particular interest was the statement of Dr. Dushman of the General Electric Company that a very simple rectifier had been evolved on Dr. Langmuir's principle that the electron emission from a hot filament in a high vacuum is unidirectional. Professor Nesbit confirmed that this rectifier type, which is of very small size, works very well for smoke precipitation.

Filling the Blast Furnace

BY J. E. JOHNSON, JR.

This is the most important single operation of the whole blast furnace process. The details by which it was carried on in early years are quite unknown to me. The earliest system of which I have knowledge consisted in throwing into the open furnace top the ore and limestone from large wheelbarrows, while the charcoal was thrown in from baskets made for that purpose, these baskets being elliptical in shape, about 4 ft. long, by 2½ ft. wide by 1 ft. deep, with hand-holds at each end. When mineral fuel was used it also was handled in wheelbarrows and even before the introduction of the closed top the use of "filling barrows" became almost universal except at charcoal furnaces. These barrows

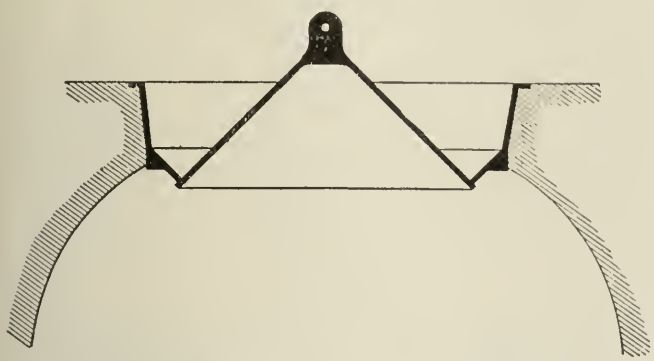


FIG. 1—SINGLE BELL AND HOPPER

(Distributes the charge in a ring next to the lining.)

are the two-wheeled type illustrated in the second article of this series.

The first method adopted for closing the top of the blast furnace was the one which has remained in use practically ever since. The apparatus is known as the "bell and hopper." In its simplest form it is illustrated by Fig. 1. It consists of an inverted cone forming a hopper set on, or in modern practice, fastened to the top of the furnace, the opening of the hopper being closed by a cone which sometimes has a rounded top and from its general shape it takes its name, the "bell." The bottom edge of the hopper is turned true in a boring mill as is the lower portion of the surface of the bell, so that they make a good fit. Into the annular space of triangular section formed by these two, the charge is dumped, by tipping forward the barrows on their own axles as a center, and when the bell is lowered the charge slides into the furnace through the annular opening formed.

During the long period in which the furnace approximated to its modern development, and ending with the Duquesne revolution, this method of filling was almost universal. The quantity of labor it involved was well recognized, and many efforts had been made to avoid this by the introduction of mechanical methods of charging. But these so almost universally had a highly detrimental effect on the operation of the furnace that they were in earlier times soon abandoned for the time-tried method universally known as "hand-filling."

It seems at first sight absurd that so simple a matter should be so obscure and should involve such great difficulties. But the spacing of the stock on the bell, the dumping of the barrows at the edge of the hopper, or on the apex of the bell, the size of the charge, and whether the ore and stone should be dumped with the coke, or separately, are all questions which may exercise an influence on the working and economy of the furnace so great as to be literally vital.

This is a field in which we have little or no theory to guide us. Our information comes solely from tedious and expensive empirical methods better described as "trial and error." Our knowledge of what constitutes correct filling comes solely from our observation as to how furnaces work with different types of distribution, and while the whole history of this vast subject abounds in contradictory experiences in the failure of apparatus and methods of operation at one plant which have made a brilliant success at another, and in other facts difficult or impossible to reconcile with one another, certain laws stand out as established by experience so nearly universal that I believe no one will question them.

These laws are: First—The distribution of each kind of stock in the furnace must be symmetrical, about not less than two axes making equal angles with each other. Second—The same proportion of lump and fine must obtain in each of the segments into which the circle of the top is cut by these equally spaced axes. Third—The distribution of fine and coarse material radially must be such as to produce as nearly as possible an equal ascent of gas through each portion of the furnace stack. To these must be added in some cases, if not in all, a fourth—The stock should be distributed not in uniform annular rings around the hopper, but in heaps, equally spaced around it.

In further explanation of the first law it may be said, on the authority of many trials, that it is not sufficient to dump all the stock symmetrically on one diameter of the furnace. No matter how carefully it may be spaced along that diameter, or even if it be dumped by tipping to first one side and then the other of the diameter, the results are unsatisfactory. This is for the reason that the tendency of this method of filling is to make two or perhaps three flat columns of coarse material separated by one or two flat columns of fines as indicated in Figs. 2 and 3, and the gas travels so much more freely through the coarse material that this descends much more rapidly than the fine, and reaches the hearth in an unreduced condition, or perhaps the opposite action takes place, and the gas being unable to penetrate the columns of fine material, does not reduce it adequately, so that it reaches the hearth improperly reduced. At all events one portion of the stock is reduced ahead of the other and the quantity of fuel which must be burned in the hearth is that required by the least reduced portion, which therefore controls the economy of the furnace. We must, therefore, dump the stock on two axes at right angles, three at 60 deg. apart, or four at 45 deg.

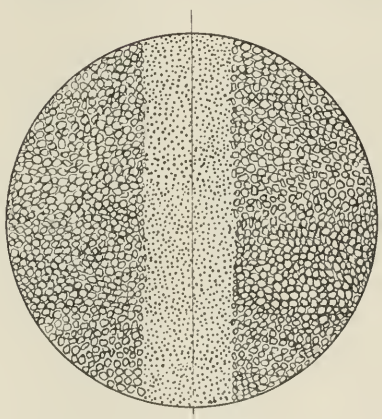

FIG. 2—SKETCH OF DISTRIBUTION OF CHARGE

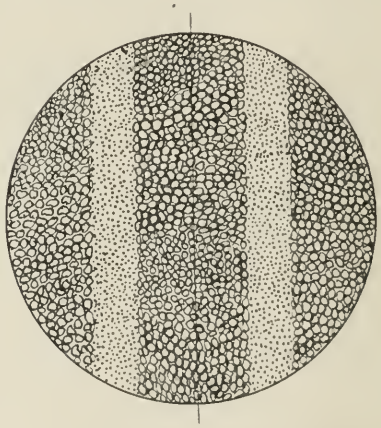

FIG. 3—SKETCH OF DISTRIBUTION OF CHARGE

When hand-filling is used it is quite easy to secure compliance with all four of the laws above stated. By dumping at four or six symmetrically placed points around the hopper, with barrows of the same sort of material, we comply with the first two laws. By the proper adjustment of the size of the bell to the diameter of the stock-line we comply with the third, and the essence of the system involves compliance with the fourth, that is, dumping in heaps symmetrically placed around the bell.

Hand-filling requires that top-fillers be carefully trained to their work, and that some pains be taken to see that they do not dump all the material on the side next to the hoist or otherwise incorrectly. This is a grave temptation to them when the furnace is driving rapidly, and they are pushed to keep up. Their succumbing to this temptation has been the ruination of more than one furnace manager who could not catch them at this trick, or stop them from it; because nothing will more quickly and completely ruin the successful operation of the furnace than filling on one side or irregularly in any way.

Even though the top fillers are well trained and faithful, there remain certain precautions to be taken even with this simple and easy system of filling. The necessity for these arises from two causes. First, the distribution and shape of the four heaps on the bell, if they are dumped consecutively, is not all alike by any means. Second, the charges are practically never made up of a number of barrows of each material divisible by the number of dumping points. That is to say, we may easily have four or six barrows of coke to the charge, to suit the number of dumping point, but this having been determined we must have a number of barrows of different kinds of ore and of limestone, depending upon the weight of the coke charge so established, and these numbers will not commonly, in fact seldom or never, be similarly divisible by four or six as the case may be, if there are twelve barrows in the round.

The lack of symmetry of the different heaps in the hopper when dumped consecutively is due to the fact that the first barrow dumped striking the hopper when it is perfectly empty spreads out laterally in both directions. The second one dumped on the diameter at right angles to it, endeavors to do the same, but the pile which it tends to make is stopped from spreading toward the first barrow dumped by the pile which the latter has formed. Consequently the contents of the second barrow spread freely on one side, but much less freely on the other. Thus the center of gravity of its contents does not lie in its dumping plane, but is deflected away from the first dumping point. The action in the case of the third barrow dumped is exactly the same, it in turn is forced around by the pre-existing heap from the second barrow. When we come to the fourth barrow the space into which it would naturally spread out laterally is cut off on one side by the heap from the first barrow, and on the other side by the heap from the third, with the result that this heap is very generally higher and always much narrower than that from any of the other barrows.

Instead of having a circle divided into four equal parts of 90 deg. each, we have the first of 100 deg., the second of 90 deg., the third of 90 deg., and the fourth of 80 deg., or some similar arrangement. This, of course, lacks very much of being the ideal symmetry which is required not only by theory, but rigorously demanded by the results of practice.

To overcome this lack of symmetry and also that due to the fact that the total number of barrows in a charge is frequently not divisible by the number of dumping points around the hopper, we have a simple means not as universally followed as it should be. This consists in shifting the first point on the bell one space each time. A very easy method of accomplishing this result is to have a number of barrows, one more or one less than an even multiple of the number of barrows in the charge. Then if pains be taken to see that the fillers go round the top always in the same direction, the first barrow dumped on each charge will always be one space away from where it was the last charge On the next, another space, and so on until within a comparatively few charges the circuit has been made, and the first barrow comes back to its starting point. This means that while each individual charge lacks much of symmetry, its initial point is revolved so that each portion of the furnace in turn receives the same treatment, thus producing what is known as "spiral filling," since any given point, such as the dumping point of the first barrow, in the successive charges as they descend through the furnace, makes a series of steps very similar to those of a "spiral" (helical) staircase.

How old this method of filling may be I do not know, it was first called to public attention in a paper before the American Institute of Mining Engineers by W. A. Barrows, then at Sharpsville, Pennsylvania, about ten

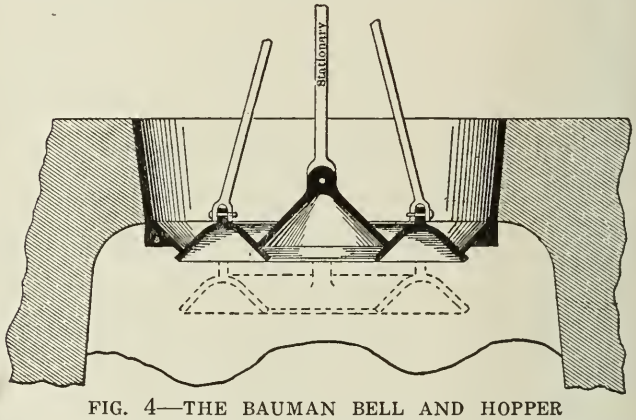

FIG. 4—THE BAUMAN BELL AND HOPPER

(Distributes the charge both in a ring next to the lining and in a heap at the center.)

years ago. On account of the important irregularities in any one charge whose origin I have tried briefly to describe, this or some similar system giving analogous results, should always be used in hand-filling.

When two top-fillers are employed another system can be employed with good results. This consists in having the two men dump their barrows at points immediately opposite one another, and at the same instant. The next time they dump opposite to each other again, but in the case of 4-point dumping this, of course, means, at right angles to the first position. The two pairs of heaps so produced are not similar but each one is similar to its opposite, and by alternating the position for the first dump the series of charges formed are all symmetrical about two axes, although the heaps on one axis are not like those on another, but these are alternated so that in the course of a double charge we even up the inequalities of one charge with those of the next. It is more difficult to secure this sort of filling than it is spiral filling, and this kind should not be used in preference to that except under unusual circumstances.

The size of the charge unit to be used, and whether the coke and ore are to be dumped all at once or separately are questions of operation rather than of construction, and will therefore not be discussed here. But in a general way we may say that coke charges range from six thousand pounds for small furnaces, up to fifteen thousand, and even eighteen thousand pounds on larger ones, while the best practice undoubtedly favors dumping the coke separately from the ore and stone.

Similarly the question of the diameter of the bell which controls the radial distribution of the stock is a question of operation, and not one of construction, since the same construction is used in both cases, with only a relative slight difference in dimensions, and this question can therefore be passed over here.

Many modifications of the bell have been made with the object of securing better distribution and better furnace work. These have sometimes been only changes in dimensions, but many other variations have been used as well. A number of these are shown in Figs. 1, 4, 5, 6, 7, 8, 9, taken from a paper by the late T. F. Whitherbee before the American Institute of Mining Engineers, vol. XXXV, entitled "Special Forms of Blast Furnace Charging Apparatus."

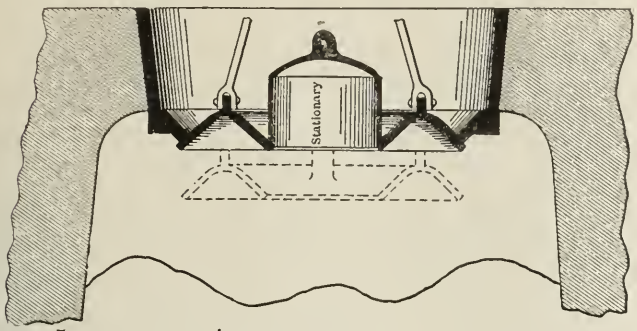

FIG. 5—FIRMSTONE'S MODIFICATION OF THE BAUMAN BELL AND HOPPER

(Distributes the charge both in a ring next to the lining and in a heap at the center.)

Fig. 7 is representative of a number of these, this being the Firmstone modification of the Bauman or double bell. The center of the cone forming the ordinary bell is cut away by an inverted cone having the same angle of slope as the bell, normally 45 deg., and the opening so formed is closed by a (nearly) stationary part commonly called by those who use this type of top, the "plug." This is not quite stationary for the reason that the inner and outer surfaces of the bell must both make a good joint. It would be impossible to maintain an adjustment of the parts which would secure this if both seats were rigid, so the plug is counterweighted until its effective weight is very small and allowed a drop of about a half or three quarters of an inch, which permits it to follow the bell down for this distance on the opening movement, while on the closing movement the bell picks it up and makes the joint on its inner seat first, then reaches its seat on the outer surface or hopper afterwards, carrying with it the plug through the distance the latter dropped in opening.

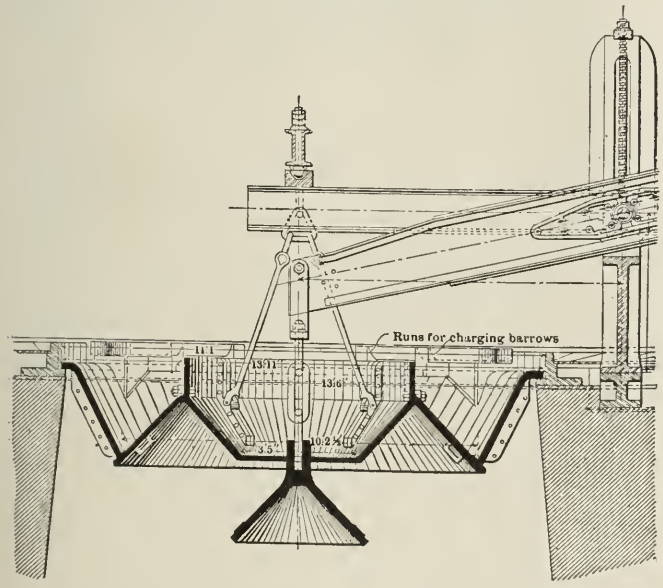

FIG. 6—THE DURHAM BELL AND HOPPER

(Distributes the charge in three ways: 1. In a large ring next to the furnace lining. 2. In a small ring. 3. In both a large and a small ring.)

Fig. 7 differs from the other types shown in that the gas outlet takes place through it, there being no flues in the side walls of the furnace. This secures an absolutely symmetrical distribution of the gas as well as of the stock, and while the former is less important than the latter, it is still very important.

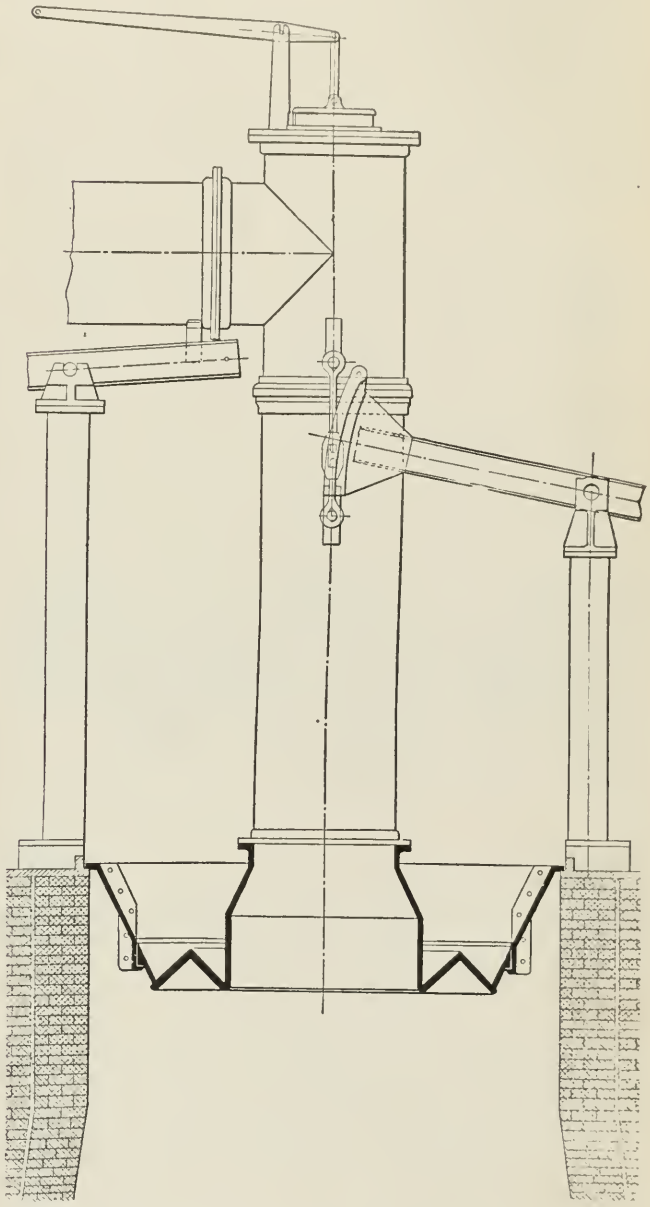

FIG. 7—THE BAUMAN-FIRMSTONE BELL AND HOPPER AT THE LONGDALE

(Distributes the charge both in a ring next to the lining and in a central heap smaller than that shown in Fig. 8.)

Tight joints in the pipe are maintained in spite of the rise and fall of the center plug by ball joints at each end of the horizontal pipe shown broken off at the left hand side of Fig. 7. The ball joint not shown is at the top of the down-comer over the side of the furnace,

while the one in the vertical center pipe is shown at the bottom of the "tee" which forms the junction between the vertical and horizontal pipes. The small amount of vertical movement necessary in the center pipe is taken up by these ball joints without any difficulty. The center pipe, with the plug fastened to it, is suspended from the tee by turn buckles, of which the one on the near side is clearly shown in the illustration.

In this type of top the lever which supports the bell can of course not be located in the center, and is therefore made double and takes hold of the bell at four points. See Fig. 10 which shows the construction used in Fig. 7 also. This type of top was used at the plant of the Longdale Iron Company practically throughout its entire life, and combined with careful hand filling gave excellent results. The great advantage of the double bell over the single is that there are two openings of different diameters, which combined with the reversed

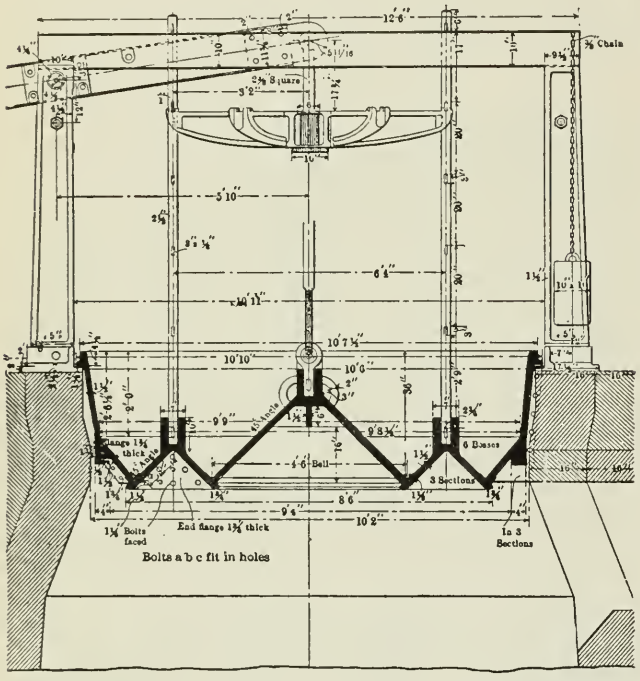

FIG. 8—BAUMAN DOUBLE BELL AND HOPPER AT THE SAUCON FURNACE, HELLERTOWN, PA.

(Distributes the charge both in a ring next to the lining and in a heap at the center.)

slopes inside and outside the bell permit the stock to be distributed more advantageously in the furnace than is possible under certain conditions with the single bell. The latter is confined to a maximum of three circular annular areas of different sizes of material, and may give only two, whereas with the double bell there can be two rings of fines, and three of coarse material, thus permitting a better distribution of the gases over the whole area of the furnace, and exposing the stock to this influence much more effectively.

This top has been used at many other plants beside Longdale, and has been very generally commended by those who have used it, but it is undoubtedly somewhat more complicated than the single bell top, and that, with the extreme difficulty of proving the advantage of one or another method of distribution on the furnace unless one of those under consideration be very bad, has prevented its general adoption.

A still more radical departure from the standard single bell top is the Langen charger in which a central piece like a plug rests in the bottom of the hopper to close it instead of being pulled up from beneath as in the standard type. The "bell," which is still so called in this case, is raised, to open it, instead of being lowered as is the regular bell. Frank Firmstone developed the double Langen charger in which the discharge took place around circles of two different diameters as in the Longdale double bell, but both openings were produced by raising the closing-pieces or bells, first one and then the other. He has described this top as applied by him at the plant of the Glendon Iron Company in the transactions of the American Institute of Mining Engineers, Vol. XIII.

The top is well shown by Fig. 10, reproduced from this paper.

Excellent results were secured with these bells, but more care and skill was necessary in designing and operating them than for the ordinary single bell, and they have never had a wide use in this country, although bells of this type are still extensively used in Germany.

There is one important difference in the conditions under which these tops had their principal use and those which predominate to-day. This is in the size of the ore, which in those times was almost entirely lump com-

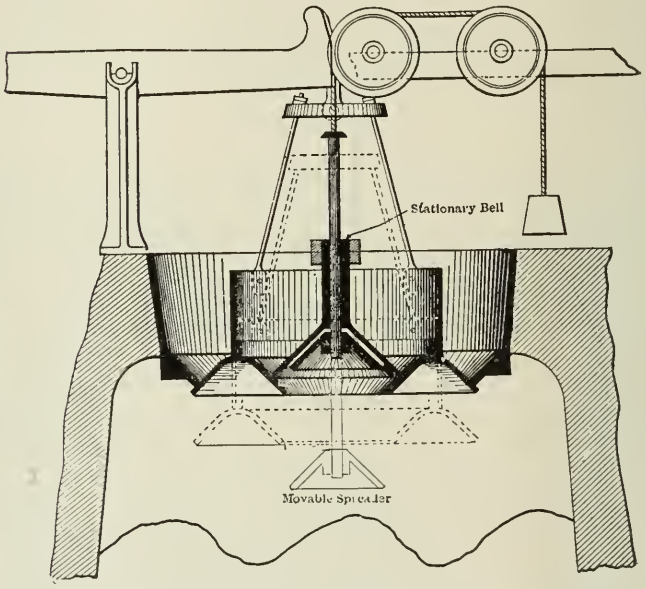

FIG. 9—THE WITHERBEE DOUBLE BELL AND HOPPER

(Five ways of distributing the charge: 1. A ring next to lining. 2. A center heap. 3. A ring next to lining and a center heap. With spreader bell down. 4. A large and a small ring. 5. A small ring.)

parable in size with the fuel, while now the ore is almost exclusively fine.

In order to have the gas travel uniformly through the stock it is very important to have the greater portion of the fines next to the walls since with *material of uniform size* the spaces next to the wall are about twice as great in proportion as they are in the body of the material, because when the high points of the individual pieces interlock with one another as they do in the mass of the material the interstices are very largely filled, but when the high points come against a flat surface the interstices are preserved complete.

By taking spheres we can determine the amount of interstices under each condition. We find that if there be a layer of spheres of uniform size arranged in close contact in equilateral triangles (the closest possible spacing) with another layer of like spheres resting in the low points of the first as they would arrange themselves naturally, the voids around the half spheres adjacent to the wall would be 65 per cent of their volume while those around the other half (away from the wall) would be 35 per cent.

This shows quantitatively the effect of the wall in

increasing the interstics under conditions in which we can calculate it, and the general nature of the effect is the same in irregular materials.

It is an old tradition in the business that the fine material must be put against the walls and it is obvious from these considerations that this is correct, and therefore the fines, that is the ore in modern practice, must go largely against the wall if we are to avoid excessive flow of gas there. Therefore we need now a single bell of rather large diameter in proportion to the stock line, but in the days of lump ores it was possible to carry this to an extreme and to have the charge column too open through the center and an excess flow of gas there, so it was desirable under those conditions to dump part of the charge in the center so that some fines would reach that part and help to obstruct it.

Mechanical Charging

Many attempts had been made to use the skip for filling purposes as well as many other mechanical appliances which would at least permit the elimination of the top fillers, usually the hardest worked, and always the ones with the greatest capacity of doing harm by improper dumping. But the results of all these early attempts had been excessively unsatisfactory because the work of the furnace was so much poorer that increased fuel consumption, diminished output, lowered quality of product, and reduced life of lining amounted

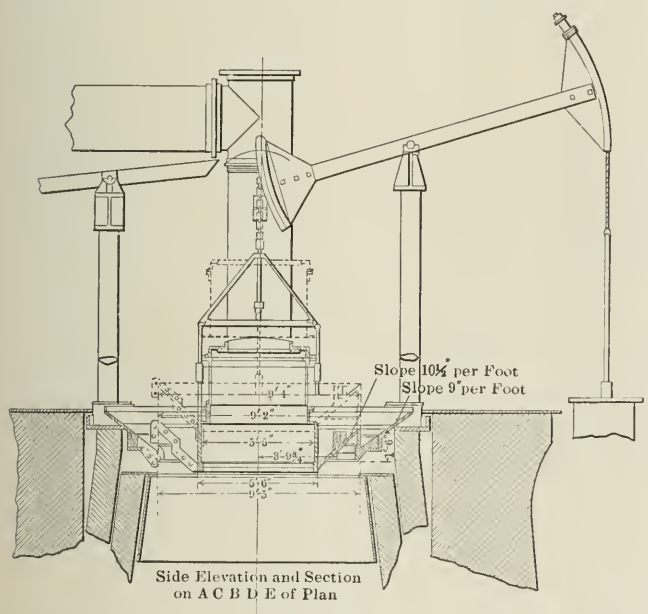

FIG. 10—DOUBLE LANGEN CHARGER DESIGNED BY FRANK FIRMSTONE FOR THE GLENDEN IRON WORKS

to very many times more on the debit side of the ledger than the slight saving of labor on the credit side.

In that early day it is well to note that the barrows were generally filled by hand shoveling, furnace operators having been exceedingly slow in realizing the value of bins. The idea that the greater portion of the work of the bottom fillers could not be reduced explains why the early attempts at mechanical filling were directed mainly at eliminating the top fillers. This made the saving relatively small, while the loss due to bad distribution may easily be, in fact generally is, of enormous proportions, and may quickly convert a profitable into a bankrupt concern.

With the rapid increase in output which took place in the early nineties and culminated in the Duquesne revolution, the difficulties of filling the furnace became more and more serious. In addition to the vast difficulty of training and keeping crews of the size necessary to do this work by hand, and of supervising their performance of it to secure good furnace operation, it became almost a physical impossibility to handle the number of barrows required, and get them on and off of the hoist platform at the top and bottom of its travel, even though the operation was kept up at the highest possible pressure for twenty-four hours a day and practically without intermission. If any interruption occurred it became more and more difficult to "catch" the furnace after the stock line had gone down below the proper level; the fillers were kept almost up to their maximum speed to keep even with it under normal conditions and obviously had to make a stern chase in order to overcome any lead that it might get by an interruption in the charging.

The great expense of this method also became more and more obvious as the number of men required increased, and looking at the matter from the financial point of view it was well worth while to make an investment which would eliminate the labor of sixty men, while the same investment to eliminate the labor of only twenty might be a very poor one. In other words the annual cost was high enough to pay fixed charges on a heavy plant investment if a suitable means could be found for filling the furnace mechanically.

The necessities of the case were so great that renewed and more extensive efforts were made to solve the problem of stock distribution mechanically, and in the middle nineties a number of designs were brought out by various engineers for the accomplishment of this purpose.

For a long time after the introduction of the bell and hopper to close the top of the furnace no effort was made to prevent the escape of the gas during the time that the bell was open for the introduction of the stock, but with the increased appreciation of the value of this excellent fuel it became more desirable to prevent even this waste, amounting to some 3 to 10 per cent of the total gas produced, and for this purpose a secondary valve or seal was sometimes provided which was closed before the main bell was opened, and opened only after the main bell was closed.

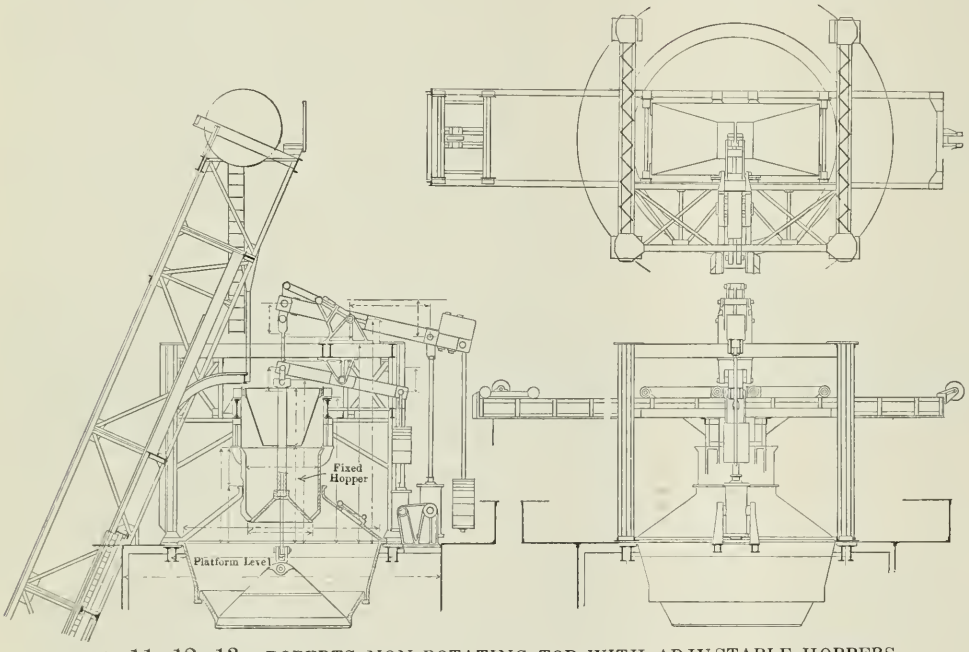
One of the earliest forms of this apparatus consisted of a huge iron lid like a pot lid, which was lowered down onto the top of the hopper before the bell was opened, and raised again after the bell was closed.

The introduction of mechanical filling made the closing of the furnace top while dumping the main bell easier and more desirable, and the obvious method of doing this was by the use of an apparatus similar to the air lock used in caisson work which in this case becomes a gas lock in which one valve opens from the outside into the lock, the other opens from the lock into the furnace. The bell having so firmly established itself as the only valve worthy of consideration for closing the furnace top it was perfectly natural that a similar bell should be used for the top valve of the gas lock, and this has become almost universal practice. This was the plan adopted at the Edgar Thompson Works, and in several with other designs.

The development of the double bell type of furnace top made the closed position of the gas seal bell the normal one, and this is greatly to be preferred because with mechanical filling it is possible to operate for a considerable period with the main bell leaking quite freely, if the gas seal be reasonable tight, and if its normal position is closed. But if its normal position be open the leaking gas meeting the air burns up through the throat of the furnace and is likely to do great damage to all the mechanism, even to the extent of softening the rod of the main bell to the point where it can no longer sustain the weight of the latter, and thus causing its loss into the furnace, an accident involving a

frightful amount of hard work and serious financial loss due to a shut down of from twelve to forty-eight hours, according to the style of top and the preparedness of the management for such emergencies.

With the gas seal bell normally closed it cuts off by far the greater portion of the leakage of gas and reduces it to an amount whose combustion can do but little harm. I have run a furnace for several days with a huge piece out of the main bell, because the hood and the gas seal being tight the quantity of gas which could escape was unimportant, but it would be impossible to operate a furnace in this condition if the normal position of the gas seal were open, because such a quantity of gas burning continually would destroy the furnace top completely. Even a much smaller leak is a very serious matter under these conditions; the result is that more work is required to keep the furnace top tight enough for safety, and main bells have to be changed more frequently because only small leaks past them can be tolerated.



FIGS. 11, 12, 13—ROBERTS NON-ROTATING TOP WITH ADJUSTABLE HOPPERS

There are two broad classes of mechanical filling as already described in the second article of this series, which may be broadly called "bucket filling" and "skip filling." There are several varieties of each, though the variations are much more matters of detail than of principle. It will be easier to discuss the points of the bucket system after considering the different types of skip filling, and we will therefore consider the latter first.

The first installation of skip filling commercially successful on a large scale was made at the Edgar Thompson Steel Works, under the supervision of their furnace superintendent, G. C. Kerr (now first vice-president, United States Steel Corporation) and chief engineer, E. E. Slick (now vice-president and general manager, Cambria Steel Company). By careful, painstaking and long-continued experimentation with model tops built exactly to scale, and raw materials crushed and sieved to the same scale, the proportions were found which would give a reasonably uniform and satisfactory distribution of the stock on the bell. A furnace was equipped with a filling apparatus of this design, and it was so successful that except for minor details nothing else has ever since been used at that plant, a record which I think is better than that of almost any other plant in the country since many of them have tried out two or three, and others very many more types of tops.

A typical double-bell furnace top is shown by Figs. 11, 12, and 13, in which the main bell and hopper, the upper or gas seal bell with the hood to connect the seat of the upper bell with the top of the hopper, and all the accessories of the top, including the skip, are well shown.

The upper bell does not need to be nearly so large as the lower one since the diameter of the latter is controlled by the size of the furnace top into which it discharges the charge, but the charge will arrange itself on the main bell in very much the same way irrespective of the size of the upper bell. In fact the small size is of decided advantage, since the nearer the stock enters through a mathematical point in the center of the furnace, the more uniform will its distribution be. If the upper hopper be large, and the stock be delivered into it irregularly by the skips, a greater or less portion of these irregularities will follow through the upper bell down into the lower. The larger the hopper the greater these irregularities may be, and the more completely they follow down onto the main bell, and so into the furnace.

Many plants have adopted what is known as the plain double-bell style of skip filling, but many have had most disastrous results with it, and others after the most careful and conscientious trials to obtain an exact distribution, have reached the conclusion that no form or design of this top is satisfactory because the distance which the materials travel is effected by the size, shape and moisture contents of the different materials and by the velocity of the skip when dumping. What is a perfect distribution on a dry day may be a frightfully bad one during a rain storm if the ore becomes wet, while a good distribution for a coarse coke, free from fine material, may give horrible results with a fine coke much broken up.

Various ingenious schemes have been used to eliminate or control these irregularities, and baffle plates without number have been tried and then discarded for the reason that no matter how good the results might be with one condition, they would infallibly be bad with some change in the conditions, such as was sure to arise within a short time, in ordinary operation. Two of these attempts may be mentioned as showing the lines of endeavor.

The Roberts top designed by Frank C. Roberts of Philadelphia is shown by Figs. 11, 12, 13, showing a central section in the plane of the skip, a front elevation at right angles therewith, and the plan view showing the receiving hopper divided into two triangular pieces, more properly half pyramids, the hopper being a truncated pyramid with its axis in the center line of the furnace, and cut in two in the central plane between the skips. Each of these half hoppers is mounted on four wheels resting on a stationary track at right angles to the plane of the skip. The treads of the wheels are wide, and their flanges set back well inside the line of the track so that the half-hoppers cannot only be moved in and out, but can also be slewed in the horizontal

plane in order to secure that distribution which, under test, seems to give the best results. In other respects the design is similar to that of any other double bell type of top.

The Rowe Top was invented by a young man of that name at a plant where they had suffered greatly from bad distribution. The extreme simplicity of his design enabled it to be applied to the furnace with only a short shut-down, and this application resulted in an immediate and decided improvement in the practice. Unfortunately no drawing of this top is available, but it may be described without much difficulty.

A vertical plate was set up in the hopper immediately under the dumping position of each skip and in its central plane; this served to divide the skip load into two precisely equal halves. To this vertical plate were fastened inclined plates which ran down into the throat of the hopper, one of them sloping from the top corner next the skipway to the opposite bottom corner, and its companion plate on the other side sloping from the top corner farthest from the skipway to the diagonally opposite corner of the vertical plates, so that the planes of the two plates made a letter X, but one line of the X was on one side of the vertical center plate, the other on the opposite side. The bottom ends of the inclined plates were located approximately at the quarter points around the circumference of the throat leading to the bell. Consequently as each skip load came up it was divided into two halves, and those two halves placed on two adjacent quarter points around the throat, similarly when the other skip came up its load was halved and delivered to the other two quarter points.

It is obvious that this action would be but little affected by a change in the velocity of the skip in approaching its dumping position, or by changes in the size, stickiness, etc., of the materials, or at least the changes so produced would be very much smaller than they would if the skips dumped directly and delivered all their material on one side or the other of the throat in accordance with variations in the conditions.

One of the earliest designs was that of M. A. Neeland, at the Ohio works of the National Steel Company, where the throat of the furnace was made quite high, and had set inside of it sloping vanes, roughly like a screw thread, which caused the material to whirl around as it descended through the throat, and as a result of this whirling it was hoped to get a uniform distribution of the stock.

Very much may be done to secure regularity by correct proportioning of the main parts of the apparatus, the location of the skips in their dumping position, the size and shape of the receiving hopper which delivers the material from both skips alike to the throat, and many other details. Each has its effect on the general result, and while many devices such as those mentioned are available, it is far better not to trust to any of these alone but to eliminate the principal irregularities as far as possible by correct design in the first place, even then there will be plenty for the secondary devices to do to secure good distribution.

These irregularities were in several cases within my own knowledge very great. It did not require accurate measurement of the heaps and gaging of the size of the materials in each portion to show this; it was obvious to the most casual observer. The really remarkable feature of the whole situation was that many furnacemen did not recognize the source of their trouble or in some cases did recognize it, but were not allowed to correct it, because to do so would reflect on a design which had been selected by their superior officer.

At one plant using lump ore which I visited about ten years ago I was taken up to the top of the furnace by the stock house foreman. Of the skip load which lay on the upper bell about two-thirds lay on the side next the skipway and consisted of all the finest portion of the load, while the one-third on the opposite side contained all the coarse! The stock house foreman said he thought that gave a very good distribution and when I asked him where the "hot spot" was of which he had told me he pointed down directly in the line of descent of the coarse material.

"Breakage of the Coke"

One of the most important factors in the whole subject of furnace operation was overlooked in the early designs of mechanically filled furnaces. This was the question of breakage of the coke. In some plants this seemed to have been almost totally disregarded. Coke was dumped from hopper cars on high trestles into bins perhaps almost empty, involving a drop of 15 to 25 ft., dropped again from the gate of the bins to the bottom of the scale car or bucket, 6, 8 or 10 ft. more, dropped from the scale car into the skip, a distance equal to the last, from the skip into the receiving hopper some 7 or 8 ft., from the upper bell onto the main bell, about an equal distance again, finally from the main bell onto the stock line, some 8 or 10 ft., if the furnace were full, up to any distance if it were empty.

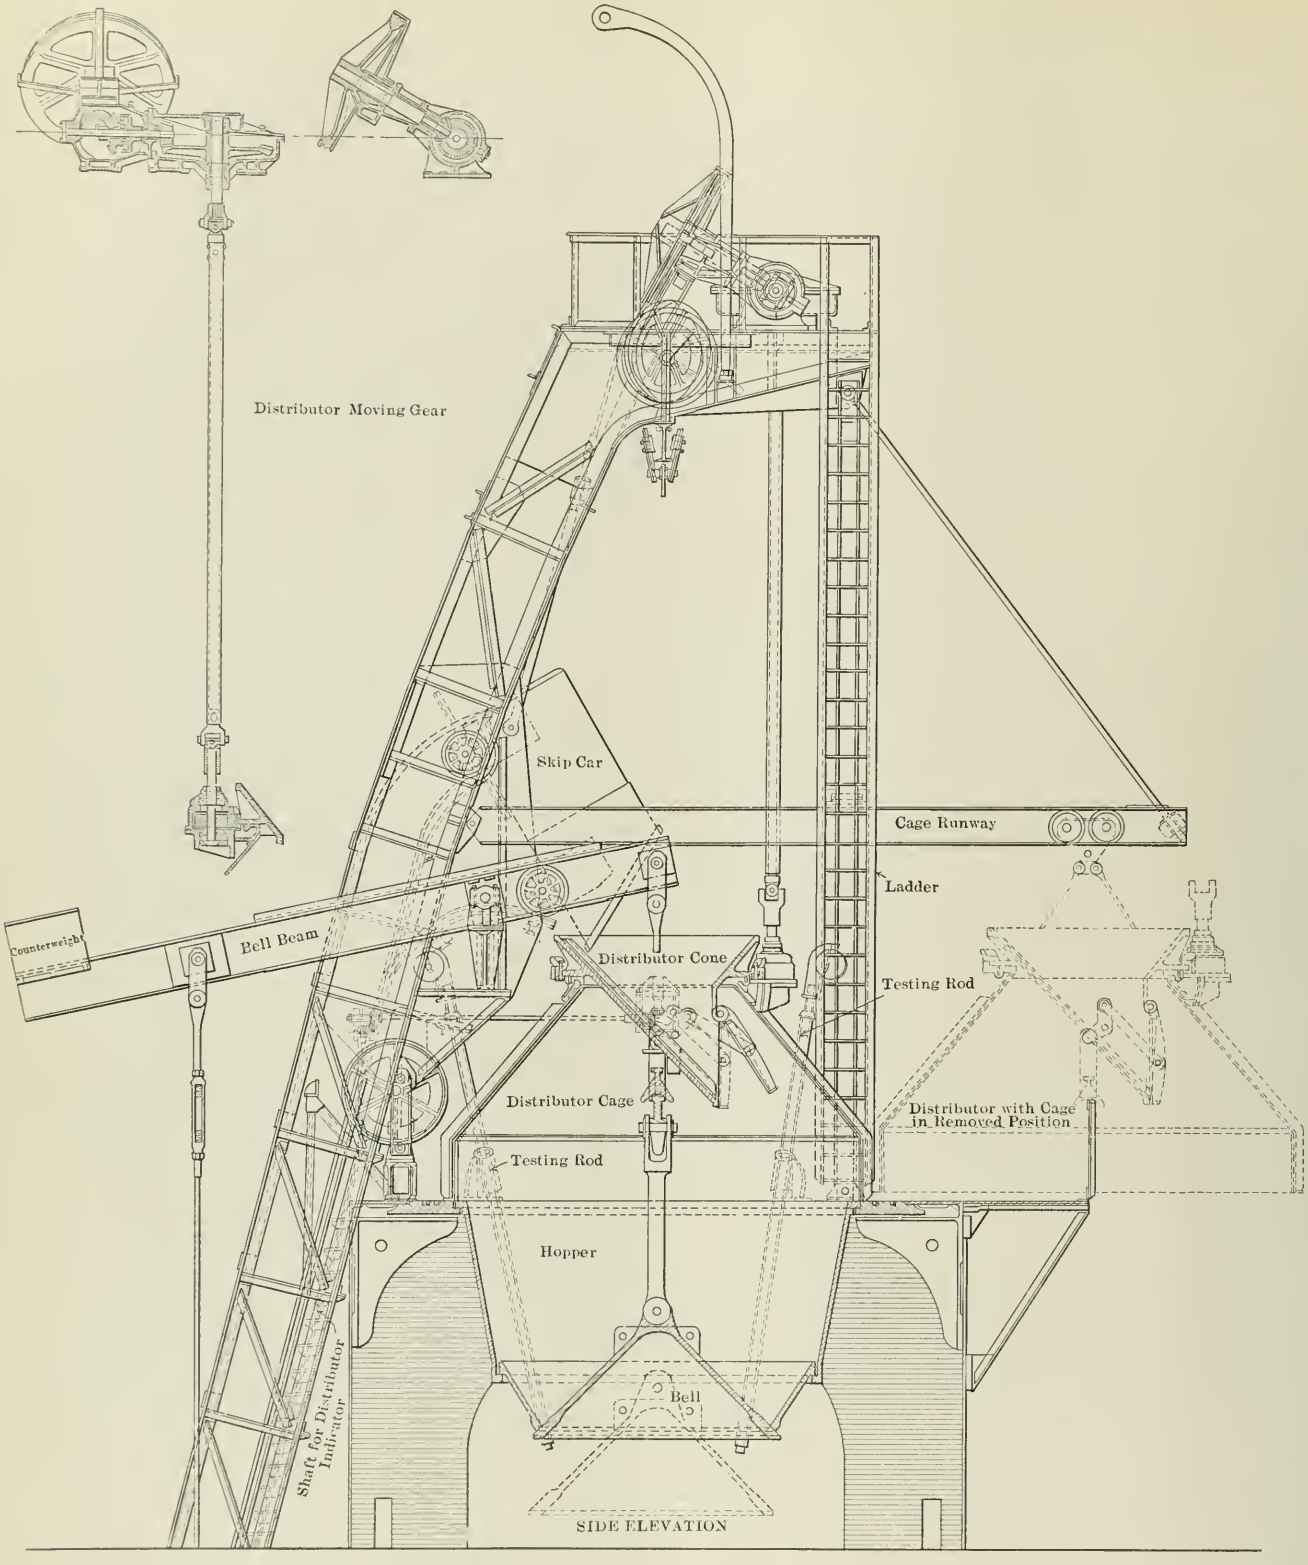
The detrimental action of fine coke in the furnace, and its much reduced fuel value, particularly for heat in the hearth, are well known, and need not be further stressed here though apparently they were overlooked by some of the furnace designers of fifteen years ago. Just how much the coke was broken up, and how much the average size of the individual pieces was reduced, what percentage of detrimental fines were made by this treatment in extreme cases, we shall never know now, perhaps it is just as well that we should not. But the general result was seen in the fuel consumption, and eventually in the cost sheet of many of these plants, while the furnace manager, who in most cases was not responsible for the design, spent many unhappy hours over these conditions for which he had in many cases to take the blame.

It will be noted that with the Duquesne system, presently to be described, the buckets were so designed as to come close up under the bins with only a short spout beneath the gates of the latter. This reduced the drop into the bucket to the minimum, and eliminated two dumpings of the coke as compared with those plants where it was transferred first to the scale car, and then to the skip before reaching the upper bell.

It is altogether possible that this feature had an appreciable influence in bringing about the early success of Duquesne as compared with many of the skip-filled furnaces built soon afterward. Now furnace managers and engineers understand this matter of coke breakage better, and it is recognized that no top should be permitted to give the coke an inch more drop than is absolutely necessary to accomplish the transfer of the stock.

In more recent years the "shatter test" of coke has been invented and attention is paid to the strength of the coke, so that more is known as to the injury done it by any given drop, but with this advance has gone the increasing realization that every unnecessary foot of drop was highly objectionable and could not fail to cause some proportionate share of increased coke breakage.

As a consequence the enormously long throats which were used on some furnaces fifteen years ago have disappeared and one of the major considerations of the present day in regard to any system of filling is its probable effect on the coke. Considering all these important points which were largely or wholly ignored or neglected the only wonder is not that furnaces did bad



FIGS. 14 AND 15—BROWN ROTATING TOP

work in the early day of mechanical filling but that they ran at all.

Rotating Tops

If the location of a given irregularity be rotated through an angle increased by a definite amount at each charge, we shall obviously obtain the equivalent of spiral hand filling and so by evening up over a number of charges the kind of material delivered to each portion of the furnace circumference shall secure the equivalent of uniform filling in each charge. Furnace tops which operate on this principle are called rotating or revolving tops.

There are in use three principal types of rotating tops—the Brown, the Baker and the McKee. All of these are patented and the whole subject has been one of much complexity, not only technical, but to some extent legal. The merits and demerits of the different types of apparatus have been the subject of acute and heated discussion. Each of them has been thrown out of use at one or more plants, and it is therefore necessary to admit that there are objections to all of them.

To state these objections as well as their advantages fearlessly and firmly is the only course open for a satisfactory treatment of this subject; however far short of this object I may come, this at least will be my aim.

The Brown Top

Although I have referred to the persistence of hand-filling as almost universal up to the time of the Duquesne revolution it is a fact that the first reasonably satisfactory apparatus for mechanical charging had been introduced several years before. The skip which dumps by turning nearly upside down, as described in the second article of this series, has been known for a long time. I am told that it was used two hundred years ago in Sweden. An attempt was made to use skip filling by Fayette Brown, the father of the late Alexander E. Brown. It is said that the furnace so filled worked irregularly in the way in which so many such furnaces have done, and the skip was therefore thrown out. In order to secure symmetrical distribution with hand filling it occurred to Fayette Brown to put a cover over the entire hopper with a single opening through it large enough to admit of dumping only one barrow, and at a certain definite location. This cover was revolved about the axis of the furnace by a mechanism driven from the hoist sheaves, so that this opening advanced one dumping space at each revolution. This, of course, forced the top fillers to dump correctly.

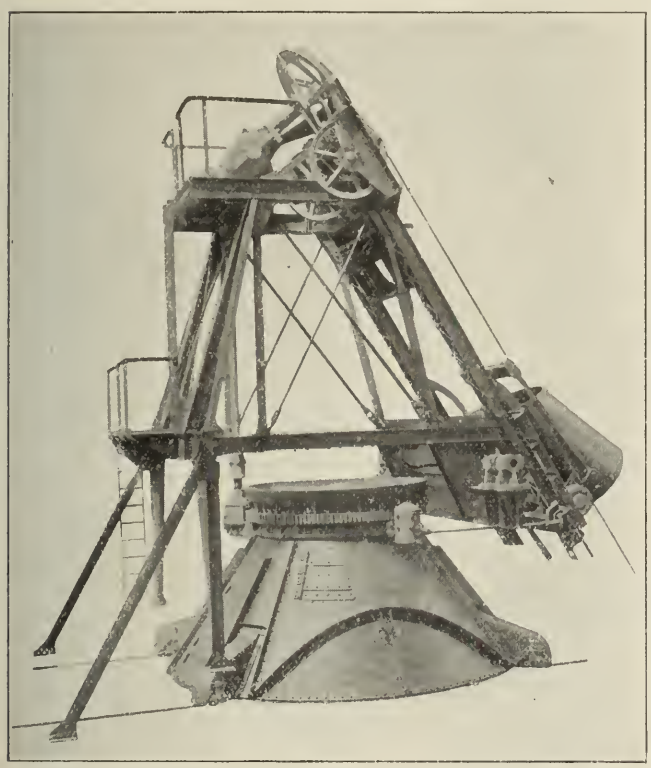


FIG. 16—BROWN TOP REMOVED FROM FURNACE

FIG. 17—RROWN TOP ON FURNACE

Many years later it occurred to Alexander E. Brown to combine this controlled system of dumping with the skip hoist by having the skip deliver into a central hopper with an outlet spout on one side, and revolving this hopper and spout around the vertical axis of the furnace by a mechanism driven from the hoisting sheaves, and this is the essential principle of the "Brown top," at least one of which was in operation several years before the Duquesne revolution, and has, I think, continued in operation from that time to this.

This top as now built is shown by the line drawings, Figs. 14 and 15, and by the photographs, Figs. 16 and 17. At the bottom of the line drawing are shown the bell and hopper; above these, on the top of the furnace proper, is the conical gas seal which acts as a support for the revolving distributor and the gears which drive it. Above the hopper is seen the skip in its dumped position, and at the top the main rope sheave, with the gears through which it drives the vertical shaft descending to the gear box just outside the distributor cone, through which the latter is revolved. The detail of the sheave and the upper gears is shown in Fig. 15.

The gas seal consists of a flap valve on the spout of the receiving hopper whose normal position is open, as shown in full lines in Fig. 14, but which is closed by the first portion of the movement of the main bell, acting through the bell crank shown in dotted lines. This gas seal is not as tight as a bell and is subject to the objection above described, that its normal position is open, so that if the main bell is leaking to a considerable extent the gas can rise through the spout and burn almost without interruption around the upper portion of the top mechanism.

There is a ratchet in the mechanism which drives the hopper when the sheave runs in one direction, but allows it to stand still when the sheave runs in the opposite direction, on the return trip; thus the hopper is rotated a definite amount with each trip of the skip.

At this point Mr. Brown introduced an admirable feature into the design. Instead of having the distributor rotate through an angle commendable with 360 degrees, so that it would always return to the same position at the end of every complete revolution, he designed it to revolve two or three degrees more or less than a quarter of a revolution, so that at the end of four movements it is some ten degrees one side or the other of the point at which it started, and only after many revolutions, representing a great number of charges, does it return to its initial point. This has the great advantage of giving not only each segment, but each fraction of the circumference of the furnace exactly the same treatment, and this is greatly to be preferred to any system which must always use the same starting point,

since in that case any irregularity due to the difference in shape of the first skip load dumped and the last, or the like, is localized in one place and may cause serious trouble, whereas if it went to each point of the circumference in turn it would do no harm.

Any mechanism at the top of the blast furnace has to operate under extremely difficult conditions. It is necessarily surrounded by the dust arising from the different components of the charge which is sharp, gritty, and destructive to the last degree, and is exposed to temperatures not infrequently above any at which lubrication is possible, and if there be a leak of the main bell so that gas escapes at all freely, the apparatus is entirely likely to be subjected to direct flame. These conditions are so severe that they alone have caused the defeat of many tops, and in the early days they undoubtedly caused many mechanical difficulties in the operation of the Brown top.

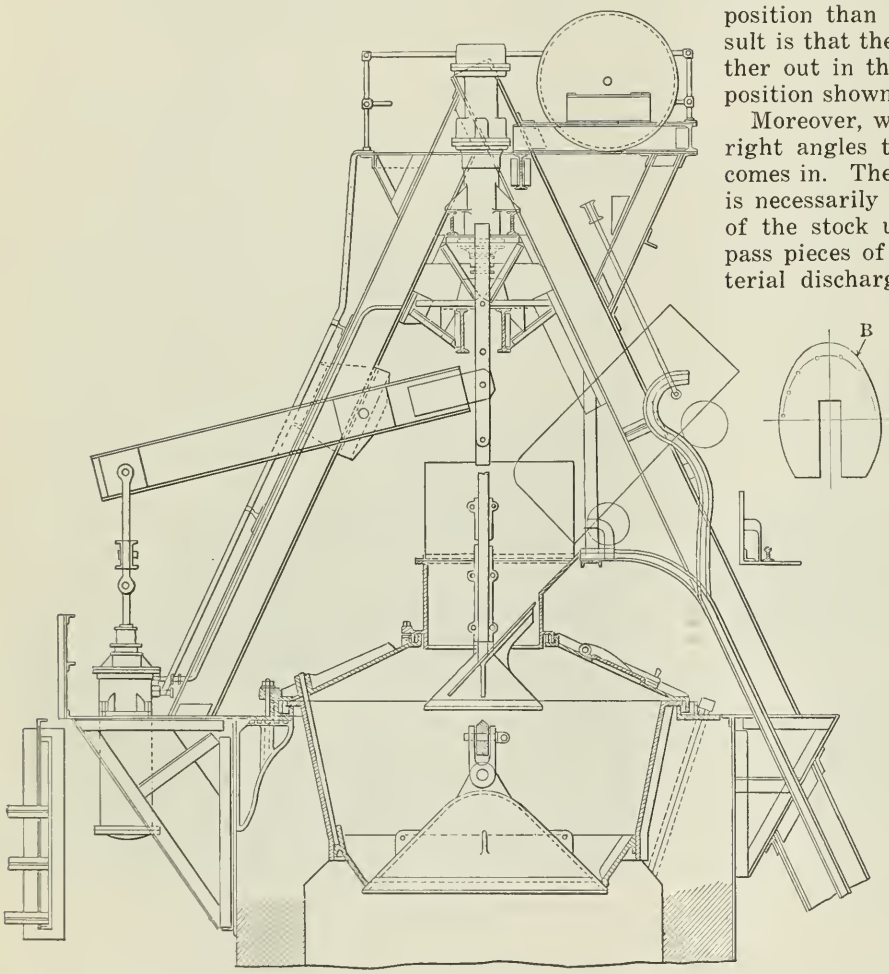

FIG. 18—BAKER ROTATING TOP

With the passage of time many of the features of the design which caused these difficulties have been overcome, and in the North where furnace tops commonly work at quite low temperatures, about 400 deg. or below, these mechanical troubles have not been so severe, but in Southern practice, with greater coke consumption, and much hotter top conditions, the Brown top has in more than one instance been discarded for the purely mechanical reason that it could not be kept in successful operation, the situation frequently being complicated by the fact that mechanics of sufficient skill to operate a mechanism of this kind successfully were, in past years, scarcer in the South than in the North.

In addition to these mechanical difficulties of operation the Brown top in spite of its appearance of perfect symmetry does not give an absolutely symmetrical distribution.

An examination of Fig. 4 will show that the line of the distributor in the position drawn is practically a continuation of the line of the bottom of the skip, so that the material discharging from the latter has only to continue on its way straight through the distributor, and is thereby delivered from it with velocity practically unchecked. But when the discharge spout of the distributor is in the position opposite to that shown, its slope is almost at right angles to the line of discharge from the skip, and material delivered upon it is therefore brought practically to a standstill, and starts again virtually from rest, so that its velocity of delivery from the distributor is very materially less from this position than from the position opposite. The result is that the material is thrown considerably further out in the hopper with the distributor in the position shown, than in its opposite position.

Moreover, when the spout of the distributor is at right angles to the position shown, another effect comes in. The spout is not a mathematical line, but is necessarily a broad opening to permit the escape of the stock under any and all conditions, and to pass pieces of scrap of considerable size. The material discharging into the hopper from the skip has a very considerable horizontal component to its velocity when it strikes the distributor, and instead of discharging down the axis of the spout, this horizontal velocity takes it over to the far side of the spout, whether the latter be turned toward or away from the observer.

The effect of this is, of course, to put more material on the side of the bell opposite to the skip than on the side next to it. In other words, in spite of the axial location of the center of the distributor the horizontal velocity of the stock imparted by the skip persists to some extent and carries the center of gravity of the pile of stock as it rests on the bell considerably beyond the axis of the furnace. That is the side of the furnace next the skip receives a considerably smaller portion of every charge than does the opposite side. Unsatisfactory furnace work has been traced directly to this cause in several cases.

The Baker Top

This may be considered as a modification of the Brown top in that it distributes the material in heaps on the main bell. It is shown by Fig. 18. Endeavor has been made in the design of this top to overcome the mechanical difficulties due to the great weight of the rotating parts, the large radius of the sliding surfaces in the Brown and the somewhat complicated mechanism required to drive it, and also to reduce to a minimum the height from which the coke is dropped so as to reduce coke breakage. The main bell, hopper, and lip ring are clearly shown by the drawing, and are of standard construction, but, as is necessary in most central types of stock distribution, the main bell is not supported on a single central rod; instead it is hung to a horizontal central equalizing beam from the two ends of which rods run up to the ends of the double main bell beam. A section of the equalizing beam, with its sharp-edged top

to divide the current of stock, and prevent any disturbing action on the descent of the latter, is plainly shown on the drawing. The main bell rod on the far side is shown broken away below the top of the upper hopper, but a short piece is shown attached to the end of the main bell beam.

In this design there is a gas seal bell practically identical with the upper bell of the ordinary non-rotating double bell charging apparatus, but in this case the bell has fastened to it a plate which is elliptical in outline and is set parallel to one side of the conical surface, and constitutes a sort of slanting piston working in the receiving hopper which is nearly cylindrical, diverging slightly at the top, as shown in the drawing. The upper bell is rigidly keyed to the lower end of its central bell rod. By means of its suspension rod the bell with its extension plate attached is rotated through a certain angle each time it is raised and lowered. When the upper bell is open, and in the position shown, the plate acts practically as a continuation of the lip of the receiving hopper and discharges the entire skip load on the opposite side of the furnace. The upper bell is then closed and opened again, which brings the deflecting plate into a position in the horizontal plane approximately to right angles of that shown. This delivers the next skip load onto the bell practically at right angles to the first one, the third is approximately opposite to the first, and the fourth practically completes the cycle, but if the "hunting tooth" effect used by Brown is desired, the cycle is not exactly completed.

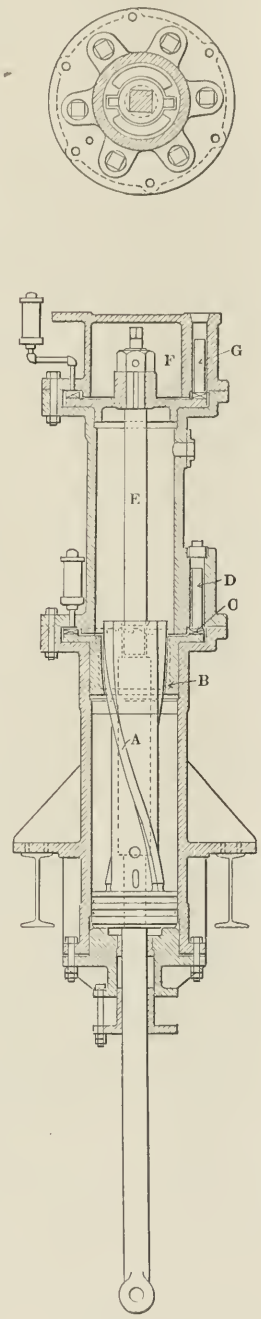

FIG. 19—ROTATING GEAR OF BAKER TOP

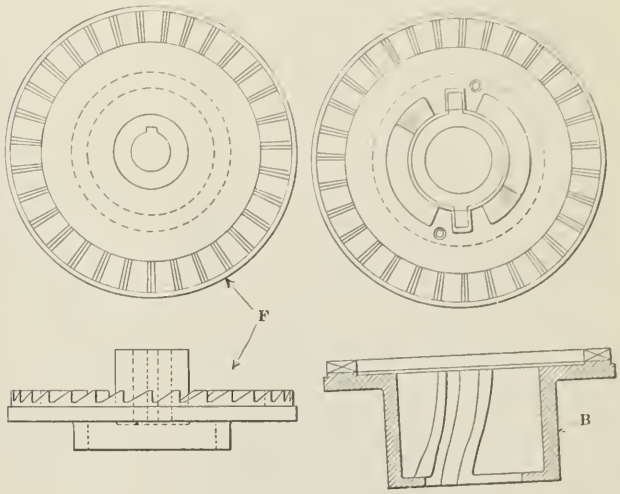
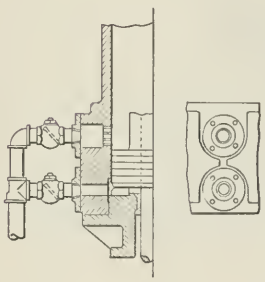
Instead of an arrangement of gears for rotation recourse is had to what is known as the rifle barrel cylinder. This device has been in use for many years for securing the rotation of rock drill bits. The cylinder which operates the upper bell is immediately over it, and inverted so that it operates directly without the intervention of levers or other devices. This makes an extremely simple design.

The operation of the rifle bar cylinder is shown by Fig. 19. The piston carries two helical vanes A which work in corresponding grooves or threads in the nut B which has ratchet teeth cut in its upper surface. These are engaged by vertical gravity pawls D in pockets spaced around the cylinder. They prevent the rotation in one direction of the nut B. A square opening at the top of the chamber on which the helical vanes are cast is an easy sliding fit on the square rod E, which carries on its top a circular plate F, to which it is rigidly keyed, and which has on its top surface ratchet teeth engaging with pawls G exactly the same as those of B and operating in the same direction.

On the down stroke of the piston, the action of the vanes forces either F to turn to the right or B to the left, but the ratchets G do not allow F to turn to right while the ratchets D do allow B to turn to the left, which it does. On the up stroke the pawls engage with the ratchet teeth C and prevent the backward rotation



of B which thus compels the rotation of the disk F in its turn.



Thus every cycle (up and down stroke) of the movement of the piston forces the bell and deflecting plate to rotate through a given angle. The amount of the rotation is determined by the pitch of the helical vanes, and the stroke of the cylinder. The latter is intended to be constant and, therefore, the angle of rotation of the upper bell with its deflecting plate is also constant.

The upper portion of this cylinder has no function except to enclose the apparatus and prevent the entrance of the grit and dirt which always abound on top of furnaces, and which have done so much to destroy charging mechanism. The cylinder is virtually a single-acting one, since the weight of all the parts acts downward and suffices for the down stroke, steam being used only for the up stroke and to cushion the down stroke.

This type of top has given good satisfaction at a number of plants, but its use has been abandoned at a number of others, since it was claimed that the benefit obtained from its form of distribution was not sufficient to offset the possibility of the small bell being stuck with its deflecting plate in one position, and dumping the stock to one point on the main bell for a number of charges, or even hours, if this condition was not discovered. For it is evident that if the small bell fails to operate between skip loads the position of the deflecting plate will be left unchanged, while there is nothing to prevent the indefinite continuance of dumping in this position. This, of course, would make the worst possible type of stock distribution, and would ruin the work of any furnace in a very few hours.

There is with this design the possibility of jamming

the deflecting plate against the wall of its slightly tapering receiving hopper by the entrance of lump material back of the plate, and while the probability seems slight, this chance, in addition to the discarding of the top by at least one large plant has proven sufficient to reduce its popularity. It is probable that the top has been successful at plants using lump ore, or a mixture of lump and fine, and less successful at plants using all fine ore, for reasons which will appear later. This is in accordance with the facts in regard to the continued use of these tops. Those within my knowledge at plants where the ore mixture is lumpy have given far greater satisfaction than those in the Lake Ore district.

The McKee Top

It has been very widely believed by many furnace men, and is even yet, that one of the essential characteristics of a revolving top is that if the revolving apparatus ceases to work it should still continue to give

FIG. 20—KENNEDY TOP

a reasonably good stock distribution. This means that dumping in heaps is barred because as explained in regard to the Brown and Baker tops, if they cease to rotate they give the worst conceivable distribution. This then implies that the stock must be dumped in annular layers as nearly uniform as possible, and that any irregularities in the layers due to the irregular discharge by the skips into the receiving hopper must be eliminated by revolving the latter.

This idea seemed to have occurred almost simultaneously to various engineers, but the credit for having first applied it successfully undoubtedly belongs to Arthur G. McKee of Cleveland.

The earliest form of this top consisted simply of a conical receiving hopper into which the skips dumped, terminating in a hopper of steeper slope below whose bottom was closed by an ordinary gas seal bell operated through a hollow bell rod which encircled the main bell rod. The hopper was mounted on ball bearings set well back from the line of the hopper, and carefully designed to keep the dust out from above, and give it ample opportunity to fall out below, holes being drilled at intervals in the bottom of the ball race to facilitate the latter purpose.

The gas seal bell, of course, requires to rotate with the hopper and therefore the hollow bell rod is provided with a small ball bearing near its upper end to permit the lower part and the small bell to rotate without interfering with the operating mechanism above.

Probably one of the most important features of the design practically is the extension of the ball track to a path well outside of the closest point on the hopper, which is carried by radial arms extending in from the upper ball race. This makes an air space between the ball race and the hopper so that unless the latter be heated to a red heat or above, the ball race still remains relatively unaffected and able to perform its functions.

This apparatus is not driven by the rotation of the sheaves through ratchet wheel and gears as in the Brown, but is provided with an independent motor operating through reduction gearing and controlled from the operating platform at the bottom of the furnace.

The general appearance of this early form of this top is shown by Fig. 20, which however is not a McKee top, but a top designed by Julian Kennedy of Pittsburg, on exactly the same principle as the McKee, but rotated by a wire rope passing around the hopper and down to the ground level, where it is moved by hydraulic cylinders or other suitable mechanism to give the desired rotation to the hopper. In principle the design is in all respects similar to the McKee.

In the McKee top contacts are attached to the hopper at four points and by means of wires carried down to the operator's platform these light indicator lamps when they come into certain positions.

In operating this first design a skip was dumped into the hopper which was then rotated through ninety degrees. The second skip was then dumped and the hopper again rotated, and so on to the fourth skip load which completed the cycle, the upper bell was then opened, permitting the charge to descend onto the main bell from which it was dumped after the upper bell was closed. The process was then repeated.

Almost innumerable modifications of this system were designed to eliminate certain irregularities which briefly are the same as those I have pointed out in connection with the dumping of barrows into the hopper in hand-filling. The location of the first skip load in the hopper and the room it occupies is very different from that of the second and third, and still more different from that of the fourth, which is likewise different from that of the second and third. Moreover with the double skip there was a serious irregularity which does not appear from the examination of a side elevation of one of these tops. From this it might appear that both skips dumped in the central plane between them, but as a matter of fact one dumps well on one side, and the other as far on the other side of this central plane, so that two successive loads are a considerable distance apart in the hopper irrespective of its rotation. It will be obvious on a little consideration that when this distance is combined with that arising from the constant angle of rotation, two adjacent skip loads may be the sum of these two distances apart, and the next two only their difference, with consequent great variation in the shape and location of the resulting heaps.

Many furnaces equipped with tops of this type while they apparently had a good stock distribution, gave extremely poor results, and as furnaces working under very different conditions showed similar results along a certain line which was not nearly so noticeable with any other type of top, it seemed reasonable to assume that the trouble was due to this type of distribution.

The furnaces filled in this way scoured out their linings in a zone twenty or thirty feet above the tuyeres, not on one side as so frequently happened with non-rotating skip-filled furnaces, but quite regularly all

around. The blast pressures were high, furnace control unsatisfactory, and fuel consumption apt to be excessive.

The real reason for these results has, so far as I know, never been worked out, but that they did exist, and that they were directly chargeable to the type of distribution used at least in one case has been demonstrated in my own experience so clearly that no unprejudiced observer could retain any possible doubt. I shall revert to this phase of the subject later.

It was in order to overcome these difficulties, whatever their reason may be, that Mr. McKee has in recent years redesigned his top so as to eliminate some of the worst irregularities. The new design is shown diagrammetically by Fig. 21.

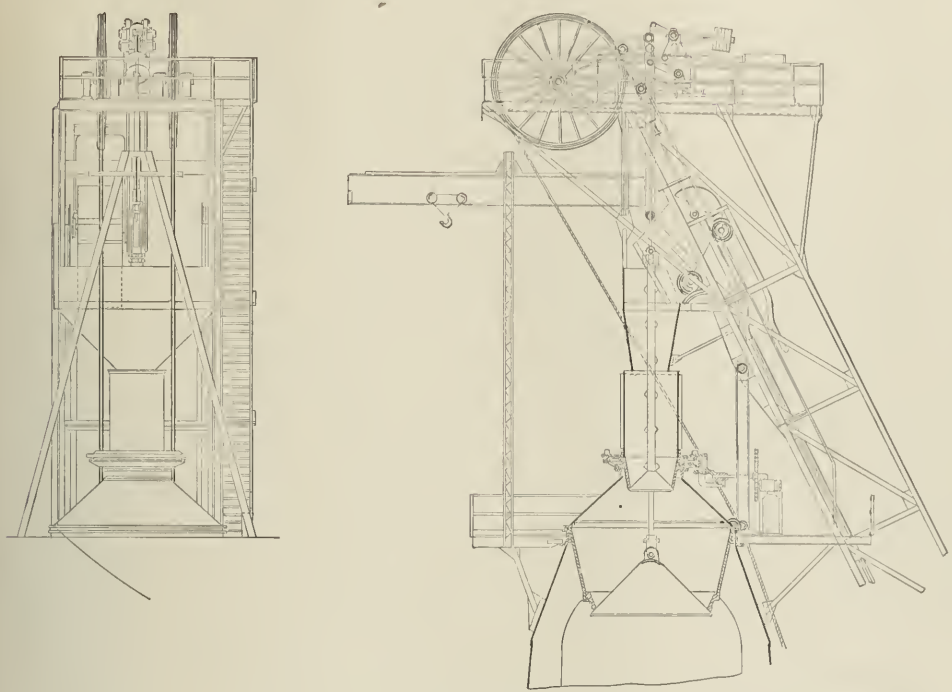


FIG. 21—RECENT DESIGN OF MC KEE TOP

The original rotating conical receiving hopper is entirely eliminated and is replaced by a flat triangular stationary receiving hopper through which each skip load in turn passes into the cylindrical rotating hopper below. This has the great advantage of practically centering the charge to begin with, and thereby eliminates some of the worst irregularities of the original design.

The revolving hopper is now being rotated preferably to six points instead of four, and so equalizes any irregularity which may occur in the discharge of the skip load into the hopper by throwing it to each one of the six successive radial positions in turn.

The design of ball races carried well away from the hopper proper, the provisions for preventing the entrance of dust and for allowing it free exit are maintained substantially as they were in the earlier design. It is no more than fair to say in this connection that mechanically this top in my experience gave a minimum of trouble, and I think that this experience has been quite general. I have not operated any furnaces with the improved design, but my information is that many of the troubles which prevailed with the older design have been diminished with this, and that the results are very much better, as is to be expected from the removal of the irregularities due to the varying distribution of the skip loads around the conical hopper.

(*To be concluded in April issue*)

The Hardening of Metals before the Faraday Society

The last meeting of the Faraday Society in London was devoted to an interesting symposium on the hardening of metals.

The president, Sir ROBERT HADFIELD, opened the discussion with an introductory address. Referring to the history of the most important "hardened" metal in the world, namely steel, he said that the world's future progress literally depended upon understanding correctly and in a scientific manner "the hardening of metals." The accurate determination of the hardness of steel alloys was now being investigated by a special research committee of the Institution of Mechanical Engineers. They were that night going to discuss the *rationale* rather than the practical applications of hardening. Having referred with deep regret to the great loss sustained by the science of metallurgy in the death of Dr. Martens, in whose honor Osmond had invented the metallographic term "martensite," he concluded by showing a specimen, probably the first to be exhibited in modern times, of an ancient piece of high-carbon steel which had been hardened by quenching. It was taken from beneath the stone pillar of Heliodorus at Besnagar, India, and it contained 99.2 per cent. Fe, 0.70 per cent. C, 0.04 per cent. Si, 0.008 per cent. S, 0.20 per cent. P, 0.02 per cent. Mn, and traces of nickel and chromium. This specimen, perhaps more than two thousand years old, was the first example of ancient steel which he knew of that contained sufficient carbon to be called steel.

Dr. G. T. BEILBY read a paper entitled "Some Recent Papers on Hardening and Overstrain in Metals, and the Bearing of These on the Author's Amorphous Theory of the Hardened State."

I. Hardening of a pure metal may be caused by cold working or by chilling.

II. Hardening of alloys, of mixtures of metals, or of mixtures of metals and metalloids may be caused by cold working, by chilling, or by the mere admixture of different kinds of molecules, either simple or compound.

In Class I, if the amorphous-crystalline theory of the hard and soft states is accepted no further explanation is needed, but in view of the fact that this explanation is not yet universally accepted, the facts and conclusions on which the theory is based are briefly discussed. The essential distinction between molecular aggregation in the two states is shown to consist in *mutual constraint in the one state and freedom of vibration in the other.* The vibrational freedom of the molecules in the crystalline state is an essential and characteristic feature of that state and inevitably leads to potential mechanical instability. Mutual constraint of the molecules in the amorphous state inevitably leads to greater mechanical stability. Mutual encroachment into each other's sphere of vibration enhances the mutual attrac-

tion of the encroaching molecules. This view falls in line with the ascertained facts as to the storage of energy in the hardened metal which is released on solution, the loss of elasticity evidenced by acoustical and other phenomena, and the electrical, magnetic and optical phenomena which probably indicate interference with the freedom of the electrons as well as with the vibrational freedom of the molecule as a whole. Further the mechanical instability of the crystalline state is shown by the ease with which the surface of even brittle, non-plastic, crystalline metals and other substances can be flowed into a smooth, hard, vitreous layer or skin. The steps in the recrystallization of the hardened metal as the temperature is raised to the point at which the whole mass is apportioned among fully developed crystalline grains supply further confirmation of the reality of the distinction between the two states.

Class II. The hardening of alloys and mixtures. If the amorphous-crystalline theory is accepted for Class I it must also be accepted for Class II, wherever the condition of flow at internal surfaces can be shown to exist either as a result of cold working or from contraction strains due to chilling. In this class the amorphous or thermally metastable state may also be produced by sudden solidification from the liquid state. Even when solidification is complete, during subsequent slow cooling molecular rearrangement among the different constitutents or phases may occur, and these changes may make either for greater or less hardness of the aggregate in whole or in part.

Mr. J. C. W. Humfrey, of Sheffield, read a paper on "The Part Played by the Amorphous Phase in the Hardening of Steel."

The conclusions arrived at in the paper may be summarized as follows:

The hard structure which can be produced in carbon steels by quenching and in certain alloy steels by normal cooling, is due to the presence of a hard amorphous solution of α iron and iron carbide, which solution may be compared to Beilby's amorphous phase formed by overstrain.

To explain the formation of this amorphous phase the author advances a theory that the passage of a substance from one allotropic modification to another of different crystalline form involves the temporary formation of an amorphous state, corresponding to the liquid phase of the modification about to be formed. In steels such a change occurs at Ar 3; and if, due to sudden cooling or to the presence of certain alloyed elements, the change-point is lowered to a temperature below that at which crystallization in the viscous mass becomes difficult, then the amorphous form will be retained in a metastable form in the cold.

The theory is supported by evidence derived from the micro-structure and physical properties of carbon steels hardened by quenching, and of alloy steels which attain a hard structure even when slowly cooled.

Professor C. A. Edwards, of Manchester, read a paper on "The Hardening of Metals by Quenching."

Steels not being the only metals which can be hardened by quenching, must be regarded merely as the higher members of a group of alloys which undergo similar changes, namely, undergo decomposition at certain critical temperatures, during which evolutions of heat occur. The critical heat changes are probably a result of the quick cooling, for if this be increased the temperature at which the changes occur is lowered and their thermal magnitude decreased; in other words, there is an increased tendency to prevent the inversion and keep the heat of the carbide change inside the cold material. Can the highest obtainable rates of cooling completely suppress the heat change? The experiments of Benedicks point in this direction and lead to the view that hardening is caused by the suppression of the heat of the carbide inversion. It has been objected that the structures of quenched steels do not support this view, but Carpenter and the author consider these to be a result of the internal stresses set up and not to indicate a difference in physico-chemical constitution. Thus the hardness produced by quenching is brought about by crystal twinning and possibly direct slipping, and the resulting formation of amorphous layers. The author meets Rosenhain's objection that the stresses set up cause no serious flow or movement in the quenched steel. He points out that Harniot has considerably increased the hardness of cylinders of silver by pressure alone without any apparent deformation. It is unnecessary to suppose with Humfrey that in passing from one allotropic form to another crystals pass through an amorphous stage; if so, where would the energy absorbed come from? On the other hand, if twinning takes place, energy would be absorbed and stored up in the amorphous layers. The facts brought forward by Dr. Desch are considered not to be opposed to the theory of hardening by twinning.

Dr. Cecil H. Desch, of Glasgow, presented a paper on "The Hardness of Solid Solutions," which was communicated by Dr. T. Martin Lowry.

Any complete theory of hardening must take into account the increased hardness which accompanies the formation of solid solutions (mixed crystals). The hardness of the elements is closely proportional to the internal pressure, a/v_2 in van der Waals' equation, and the hardness of solid solutions has been attributed to an increase in the internal pressure. Native copper has been shown by the X-ray method to have a simple cubic space lattice. Gold and silver are probably quite similar, and the atomic volumes of the two metals are almost identical. It is, therefore, difficult to see how any considerable distortion of the space lattice can occur when the two metals are alloyed. The density is unchanged by alloying, and the metals interpenetrate freely by diffusion, but the hardness is twice as great as that of the single metals. Transparent isomorphous mixture of salts may be obtained without optical evidence of internal strain, and yet exhibit increased hardness. A great difference in the attractive forces between the atoms is not easily conceived in the simple case of silver and gold. No theory at present accounts satisfactorily for the facts.

Dr. Cecil H. Desch also contributed a note on "Crystal Twinning and the Martensitic Structure."

The theory that the hardness of quenched steels and other alloys is due to repeated twinning is open to serious objections. It is shown that a twinned martensitic structure may be obtained in metals and alloys which are not hard. A very slowly cooled low-carbon steel, previously overheated, showed a characteristic martensitic structure in pearlite of the usual hardness. The hard constituents of quenched alloys may or may not exhibit twinning, and the latter is at most an accompaniment, not a cause, of the hardness.

Mr. Andrew McCance, of Glasgow, contributed a paper on "The Interstrain Theory of Hardening," which was read in abstract by the secretary.

Only two real allotropic forms of iron exist—gamma iron, which can dissolve carbon and is non-magnetic, and alpha iron, which does not appreciably dissolve carbon and is magnetic at ordinary temperatures. "Beta iron" is only alpha iron which has lost the property of ferromagnetism from purely thermal causes, and the pseudo-change-point at A2 is due to a variation in the specific heat which always accompanies this transition. Gamma iron cannot be made ferromagnetic by any treatment such as permanent deformation, etc. Metals

after deformation are best described as being in a condition of "interstrain," since there are facts which cannot be explained by the theory of a hard amorphous vitreous phase, such as the dissimilarity in magnetic properties of strained gamma and strained alpha iron and the hardening effect on metals of high fluid pressure without any resulting deformation. Hardening by deformation results from purely structural causes which affect the crystalline state.

In steels during cooling two transformations can take place: (*a*) the change in the iron from gamma to alpha, and (*b*) the change in the state of solution of the carbon. Quenching suppresses (*b*) but allows (*a*) to proceed, and the alpha iron formed under this condition is interstrained and hard. This accounts for the magnetic properties of quenched steels and for the fact that the hardness reaches a maximum independent of the carbon content. Austenite, which is soft, results when both transformations are suppressed, but when tempered at about 250° C., or immersed in liquid air, the transformation from gamma iron to alpha takes place suddenly and an increase in hardness corresponds with the formation of the interstrained alpha iron.

Professor HENRY M. HOWE, of Columbia University, contributed to the discussion a paper on "Hardening with and without Martensitization," which was communicated by the president.

Of the six methods of hardening according to the author's classification, five are martensitizing and one non-martensitizing. The former ways of hardening are (1) that of carbon steel by rapid cooling; (2) that of steels with an intermediate proportion of manganese or nickel by air or other moderately slow cooling; (3) that of Maurer's austenitic manganese steel by cautious reheating; (4) that of 25 per cent. nickel steel by liquid-air cooling; (5) cold deformation of any ductile metal. The non-martensitizing way of hardening is holding manganiferous ausentie (Hatfield's manganese steel) shortly below the transformation range (e. g. at 550°), whether the cooling thence be fast or slow. It is shown how all these methods of hardening but the last can be explained by the amorphous theory. This is described as referring the hardening to the presence of a very great proportion of iron made amorphous by the formation of innumerable slip bands, caused by the sudden expansion due to the starting of the $\gamma \rightarrow \alpha$ transformation at innumerable nuclei, and its arrest by the pressure thus caused. The martensitization which occurs in all these cases (formation of the very hard acicular constituent known as "martensite") tallies with the conception of innumerable slippings. The amorphous theory cannot explain the sixth method of hardening (if this also takes place in the absence of carbon—this is being tested), because at such high temperatures amorphous iron should be able to recrystallize. The γ theory, which ascribes hardness and brittleness to martensite because it is an undercooled solution of γ in α, is shown to be unsatisfactory in all of the six cases. If hardening No. 6 takes place in the absence of carbon, the author considers the β (an alleged intermediate allotropic modification of iron) more credible than the amorphous theory, in spite of the surprising slightness of the discontinuity in the cooling curves at the supposed β-α transformation point.

Dr. T. M. LOWRY and Mr. R. G. PARKER presented a "Note on Metallic Filings."

They suggested that these were probably cold-worked in an extreme degree. They regarded the remarkable properties of fresh filings of the silver-tin "dental alloy" as due to the presence of a large proportion of Beilby's amorphous phase. The change of density produced by "ageing" these filings at 100 deg. C. is larger than in the case of pure metals, but experiments now in progress have shown that other metallic filings exhibit analogous changes of density when annealed at 100 deg. or even at 80 deg. C. These temperatures are much below those given by Beilby for annealing temperature of hard-worked alloys, and are very much below the annealing temperatures commonly used in metallurgical work.

Dr. J. E. STEAD, in a communication made by the president, stated that in his opinion we had not sufficient data on which to found any definite conclusion as to why steel is hardened by heating to above Ac 1-2-3 followed by quenching, but it was certain that the carbon was mainly responsible. The different behaviour of hardened and annealed steel when treated with chemical reagents proved that there was a difference in their chemical constitution. The allotropic theory could only be regarded as a tentative hypothesis. The solid solution hypothesis too might be one of several pointing in the right direction. The internal stress hypothesis also might be more or less correct, but it must not be forgotten that 0.9 per cent. carbon steel could never be made intensely hard merely by stressing and distorting in the cold. Again, iron saturated with 1.7 per cent. phosphorus, the phosphorus in this case being in solid solution Fe_3P in iron, is difficult to drill, while Cleveland pig, or any grey iron containing even 2 per cent. or more phosphorus, in which case the Fe_3P is in a free state, can be readily machined.

Dr. Stead opposed the view that twinning was an indication of hardness, nor did he consider that martensite probably consisted of a mass of twin laminæ. The same steel containing 0.9 per cent. carbon, whether quenched from 750 deg. C. and barely martensitic or quenched from 900 deg. C. with a pronounced martensitic structure, is equally hard, in spite of the fact that the internal stresses in the second case must be much the greater.

In conclusion, although we had not sufficient data on which to base dogmatic conclusions, there could be little doubt that on the carbon condition mainly depended the extreme hardness of steel.

Mr. ANDREW MCCANCE in a written communication emphasized the difficulty of explaining the hardness produced without deformation by the action of high pressures on metals, and the magnetic properties of strained α and γ iron, by Dr. Beilby's theory of the amorphous phase. Again, had it been shown experimentally that the amorphous state was actually harder than the crystalline for any substance at the same temperature? Mr. McCance also dwelt on the difficulty of correlating magnetic properties with the amorphous phase theory, and he criticized the way in which Mr. Humfrey met the difficulty by assuming that in the crystalline space lattice it was the *molecules* which were regularly spaced. Mr. Humfrey's view that structureless martensite was formed when all the austenite had been transformed to amorphous α iron, while the more prominent structure obtained from a higher quenching temperature was due to the retention of much austenite, was not in accordance with experimental evidence.

The president, in opening the general discussion, was pleased to notice that Dr. Stead emphasized the fact that the main factor in the question of the hardness of iron alloys was the presence of carbon. It was also evident that Professor Howe, who had kindly sent a communication all the way from America, was also coming back to a carbonistic theory. Sir Robert Hadfield felt so strongly on this matter that he had offered a research prize of £200 in order to stimulate the study of the carbides of iron and of iron alloys generally.

Professor T. TURNER said that the subject under discussion was of extreme importance. Sometimes we required a metal to be soft, and sometimes its value de-

pended on its being hard; we therefore want to know the reason why it is hard or not hard. He agreed with Dr. Beilby that we should know more of the molecular structure of the metals. There were two kinds of hardness which should be kept distinct from each other in one's mind. One was the hardness caused by mechanical deformation, and the other was the hardness brought about by a chemical change which produced a closer packing of the molecules of the material. Still it must be borne in mind that when a metal is hardened its density increases to only a very small extent. Another thing which altered molecular distance and produced hardness was the formation of solid solutions. There must be enormous forces brought into play when one substance dissolves another, and it is natural to assume that closer packing of the molecules results. Professor Turner explained most of the changes in hardness which took place in various steels by the solution or the segregation of the various carbides at different temperatures.

Dr. W. H. Hatfield pointed out that at least three of the theories brought forward that evening were really an indirect result of Beilby's work on the amorphous theory. Dr. Hatfield had independently arrived at views similar to those of Mr. Humfrey. It seemed obvious that when γ iron changes to α iron it passed through the mobile or amorphous phase; but during quenching the amorphous phase was presumably side-tracked and remained unchanged, thus producing hardness. Dr. Hatfield pointed out objections to his and Mr. Humfrey's views.

Mr. T. G. Elliott was glad to observe a revival of interest in carbon as a factor in the cause of hardness, and expressed the view that an examination of steels under heat treatment would throw great light on the subject.

Dr. F. J. Brislee asked Dr. Beilby whether the passage from the amorphous to the crystalline stage would have a definite transition point, and whether, in the case of aluminium, this point was identical with the annealing point.

Mr. S. A. Main pointed out that the various theories advanced that evening were qualitative rather than quantitative. What was badly wanted was a definite scientific unit in which to express hardness, especially extreme hardness.

Sir T. K. Rose asked Professor Edwards about the production of twinning in tin by bending. "How long did he leave the tin before examination"? He asked this question because tin anneals itself at the ordinary temperature in 24 hours.

The president, in reply, agreed with Mr. Main's view that a definite scale of hardness, which was independent of any particular method of estimation, must be arrived at. He mentioned that when measured by the rebounding test quartz was the hardest material known. Many of the theories advanced that evening must be wrong, because they required that the projectile of a 15-in. gun, which weighed a ton and had a glass hard surface, was in a state of strain. This was improbable, as the projectile could cut through 15 in. of steel without being fractured.

DINNER OF AMERICAN ELECTROPLATERS' ASSOCIATION

American Electroplaters' Society

The New York and Newark branches of this flourishing society held their sixth annual banquet at the Broadway Central Hotel, New York City, on the evening of February 20. Two hundred were present. Mr. de Joannis, editor of *The Brass World*, presided as toastmaster. Prof. J. W. Richards, of Lehigh University, honorary member of the society, charged the electroplaters with being "The Daddies of Electrometallurgy," and proved his thesis by referring to the development of electrometallurgy from the electroplating art. Mr. A. K. Selden, of the Crocker-Wheeler Electric Company, described the characteristics of "The Modern Dynamo." Dr. Hiram Lukens, of the Harrison Laboratory, University of Pennsylvania, described briefly the electro-analytic methods which platers can use to determine the metal content of their solutions.

The society has 14 branches and over 600 members. Its members are chiefly foreman electroplaters, and the society has been of great educational value to them. Mr. Walter Fraime, of Dayton, Ohio, is secretary, and the next meeting will be at Dayton, in the plant of the National Cash Register Company the first week in June. Everybody interested in electroplating is invited to attend the meeting.

At the meeting of the Newark Branch, March 19 next, Prof. J. W. Richards will lecture on "The A. B. C. of Electroplating."

Annual Meeting of American Institute of Mining Engineers

The 110th meeting of the American Institute of Mining Engineers was held in New York City from Monday to Wednesday, February 15 to 17, 1915.

The business meeting was held in the morning of Tuesday, with President B. B. THAYER in the chair. The various reports were submitted and accepted. The results of the annual election of officers were announced as follows:

Mr. WILLIAM L. SAUNDERS, president of the Ingersoll-Rand Company of New York City, is the new president of the Institute. Mr. Charles F. Rand, president of the Spanish-American Iron Company, and Mr. Benjamin B. Thayer, president of the Anaconda Copper Company, are the past-presidents on the Board. Messrs. Sidney J. Jennings and Philip N. Moore were elected vice-presidents. It was announced that the proposed amendments to the constitution had been adopted by a majority of almost four to one.

The feature of the social functions was the annual dinner, held at the Hotel Astor on Tuesday evening. It was exceedingly well attended, some 300 members with their ladies being present. The feature of the after-dinner speeches was the brilliant address of the president, Mr. B. B. Thayer, who reviewed the past year's work in the Institute, announced that Professor James F. Kemp had been elected an honorary member of the Institute, and introduced the new president, Mr. W. L. Saunders, as toastmaster. Speeches were then made by Mr. Gans S. Dunn, Mr. Job Hedges, Dr. R. W. Raymond and Mr. John C. Montgomery.

W. L. SAUNDERS, PRESIDENT AMERICAN INSTITUTE OF MINING ENGINEERS

Professional sessions for the reading and discussion of technical papers were held in the forenoons and afternoons of the three days, often two sessions simultaneously in adjoining rooms of the Institute's headquarters. All were very well attended. In the following report chiefly those papers which are of metallurgical and chemical interest, are noted.

Safety and Sanitation

The first meeting, on Monday morning, was devoted to safety and sanitation. Mr. Arthur Williams, of the New York Edison Co., presided. The four papers presented were: "Safeguarding the Use of Mining Machinery," by Frank H. Kneeland; "Safety Methods and Organization of United States Coal & Coke Co.," by Howard N. Eavenson; "Housing and Sanitation at Mineville," by S. Le Fevre; "Enlarging the Worth of the Worker and the Perspective of the Employer," by J. Parke Channing.

Iron and Steel

At the iron and steel session, held in the afternoon of Monday under the auspices of the Iron and Steel Committee, Dr. Albert Sauveur, of Harvard University, presided.

High-Blast Heats in Mesaba Practice

A paper on "High Blast Heats in Mesaba Practice," by WALTHER MATHESIUS, of the Illinois Steel So., South Chicago, Ill., was presented, in the absence of the author, by Mr. W. A. Forbes. The use of high blast heats on furnaces melting Mesaba ores is still the exception, the average blast temperatures carried on Mesaba stacks seldom reaching 1100 deg. F., while a large number of Mesaba furnaces have been and are operated on very low blast temperatures, ranging between 800 deg. and 1000 deg. F.

"Actual practice in recent years has proved a different conclusion, having shown that a considerable coke saving is still obtainable when the heats are raised above the 1100° line . . . During the last year, the blast temperatures of two of the Bessemer furnaces at the South Chicago plant of the Illinois Steel Co. were raised above the 1100° line, and for many months temperatures from 1100 to 1300° F. were employed, with the result that the coke consumption was reduced to extraordinarily low figures without causing any operating difficulties . . . Since it has been shown, therefore, that with proper furnace conditions it is not only possible, but profitable in coke economy, to carry high heats on Mesaba furnaces, the next problem is to generate these heats in the most efficient way, and without losing through inefficient stove operation the advantage thus to be gained. In other words, the problem of adapting furnace lines, raw materials, and operation to the new practice having been proved capable of solution, efficient heat generation, through suitable stove construction and operation, is of paramount interest to-day."

The author then discussed the provision of new stove equipment. The erection of a fifth stove is thought by many blast-furnace managers the best means of increasing stove-capacity, for two obvious reasons: (1) because it can often be done with practically no other changes to existing equipment, and (2) because it insures a greater regularity of blast temperature.

But a fifth stove means not only greater complications of operation, but a loss in efficiency due to the increase of radiating surface. The benefit of the regular maintenance of higher heats is obtained at the expense of stove efficiency, because the chief evil has not been removed, namely, the accumulation of flue dust in the stove checkers, which constitutes the greatest impediment to efficiency in stove practice. The only way to eliminate this definitely is to prevent the flue dust from entering the stoves, *i.e.*, to wash the gas thoroughly. In Mesaba practice the washing of the gas is especially important.

"It is the use of washed gas which has made possible the construction of stove linings with a view to stability and heat economy only, and without regard to the consideration of stove cleaning, which, if the gas be dirty, must become the prime factor in determining the checker-work construction. The checker openings, which, where unwashed gas is used, are usually 9 in. square, can, with washed gas, readily be reduced to as small a size as the draft will allow. The checker walls, which, with unwashed gas, are not considered

safe when less than 3 in. in thickness, can now be reduced to the limit set by the size of checker openings as determined by the proper relation of total brick volume to surface, and by the ability of the brick manufacturer to produce a strong, substantial firebrick. In this way, the heating surface of the checker work is increased, for instance, more than 50 per cent. by reducing the checker openings from 9 to 4 in., and the thickness of the checker walls from 3 to 2.5 in. At the same time, this construction eliminates the dead portion of the brick work, in the center of the thicker checker walls, which does not participate in the heat exchange, as is proved by the fact that during the ordinary heating and blowing periods it undergoes hardly any change of temperature.

"By using washed gas and changing the stove linings along the lines indicated above, any furnace plant can increase the heating capacity of its stove equipment without adding to the radiating surface. In many cases an increase which will fully meet all heat requirements can thus be obtained.

"With higher stove temperatures, better insulation of the stove shell gains importance. It can be obtained by making the outer brick walls thicker, and using for them two kinds of brick: a porous kind of highly insulating quality, next to the shell; and, inside of this, a course of common firebrick (except in the combustion chamber, where a lining of highly refractory brick is required). Under no circumstances should the depth of the insulating wall be sacrificed to the desire of increasing the heating surface. To get an idea of the heat saving which can be expected from a better insulation, one has only to consider that in most stove plants the radiation losses amount to fully 20 per cent. of the total heat generated.

"If sufficient heating capacity cannot be obtained within shells of a given size, the only remedy is to enlarge them, by increasing either the height or the diameter. In building new stoves a larger diameter should be chosen; and on existing units an increase in height is generally feasible and sufficient.

"With proper equipment and clean gas, stove operation becomes an entirely different problem. It is no longer largely a question of crowding as much gas and air into the stove as possible. The scientific rules of combustion can now be applied, and the stoves can be heated with a minimum amount of gas by complete combustion, proper draft regulation, and an even distribution of the combustion gases and air over the entire heating surface."

The author then discusses the combustion of washed gas and the distribution of the gases and gives in the final part of his paper a very interesting thermal analysis of the performance of No. 4 Blast Furnace at the South Works of the Illinois Steel Co. during the month of June, 1914.

The weight of materials passed through the furnace was burden 31,645 tons, limestone 6154 tons, coke 13,006 tons, product (including scrap) 17,319 tons, slag 7,811 tons, flue dust 691 tons, blast (excluding moisture) 51,592 tons, moisture in blast 539 tons, top gas (excluding moisture) 72,360 tons, moisture in gas 4,665 tons.

The final heat balance sheet is given in Table I.

TABLE I.—HEAT BALANCE SHEET FOR ONE TON OF PRODUCT

Generated

By	B.t.u.	Per Cent
Combustion C to CO	3,995,000	31.1
Combustion C to CO_2	6,754,000	52.6

Total		12,848,000	100.0

The paper was discussed by Mr. J. E. Johnson, Jr., Dr. J. W. Richards, and Mr. W. A. Forbes and considered to be a highly valuable contribution to the metallurgy of iron.

Finishing Temperature of Rails

A paper by W. R. SHIMER, on the "Effect of Finishing Temperatures of Rails on Their Physical Properties and Microstructure" gave a summary of the results of experiments conducted by the Bethlehem Steel Co. during the past year.

The rails were rolled from reheated blooms. All the rail blooms were charged hot in a reheating furnace and brought up to about the original ingot-rolling temperature before rolling into rails. These rails gave better results in deflection, withstood a greater number of drops before breaking, and showed greater ductility than rails of identically the same composition and section which were rolled direct from the ingot.

The results of the very numerous tests are given in tables and the paper is profusely illustrated with microphotographs. While the results as to the advantages of reheating blooms on the properties of the rails seem conclusive, there are no conclusive results as to the best finishing temperature.

"There was a variation of 500 deg. F. in the finishing temperatures and a variation of 1.34 in. in shrinkage. Even with this wide range in temperature and shrinkage, it was impossible to determine, from the results of the respective tests, at what temperature a rail should be finished in order to obtain the best results, since all the tensile and drop-test results recorded are good, and practically identical. The results show it is equally impossible to decide what microstructure and shrinkage are desirable.

"Further, from the results of this investigation we have learned that rails rolled from reheated blooms are more ductile than those rolled direct from the ingot, regardless of their finishing temperature. Also, we have learned to be cautious with regard to judging from the microstructure as to the temperature at which a rail was finished and to be careful in drawing conclusions from the microstructure, alone, in rail-failure investigations. The microstructure appears to be controlled more by the rate of cooling from above the critical point than it does by the temperature at which it was finished. In regular practice rails cool uniformly, since hot rails are going to the bed continually, and therefore the microstructures do not vary as much as they have in this experiment."

Mr. W. R. Shimer's paper was discussed by Mr. Wm. R. Webster, Prof. Henry M. Howe and Dr. J. K. Burgess.

Sound Steel Ingots and Rails

A paper by Dr. GEORGE K. BURGESS, of the Bureau of Standards, Washington, D. C., and Sir ROBERT A. HADFIELD, of London, England, reported tests of rails rolled in one mill according to American practice, from eight ingots manufactured by the Hadfield special-feeding process (this journal, Vol. 11, p. 79, 1913), and a comparison ingot, supposed to represent the usual type of ingot from which rails are made in this country. The results are given in tables and diagrams in considerable detail.

"The examination of the split ingots shows the great superiority of casting large end up and feeding by the Hadfield special process, such an ingot being physically sound and uniform throughout and practicaly free from chemical segregation.

"The examination of the rails shows that for ingots cast by the Hadfield process, those cast large end up will give rails of uniform quality free from flaws of all kinds; those cast small end up may show a soft region in the web of the *A* rail but are otherwise sound. Those cast in the ordinary manner from piping or otherwise unsound steel may or may not give sound rails, depending upon the condition of the steel.

"In addition to the certainty of producing all sound rails by the special-feeding process from ingots cast large end up, there is a great saving in metal and a consequent increase in percentage of sound ingot available for rails—in these experiments an average of 90 per cent. for ingots Nos. 2, 3, 4, as compared with about 50 per cent. for the piping ingot and an uncertain amount from the rising type.

"The usual physical and chemical tests do not appear to give an adequate measure of the quality of rails. For example, the results of the tensile and drop tests and chemical analyses would not separate the sound from all the unsound rails here examined.

"The question may be asked, Is it not worth while to use, in the manufacture of rails, only sound steel which is cast and rolled in such a manner as to make practically every rail a sound and safe one? We believe this can be done without excessive cost."

The paper was discussed by Dr. Sauveur, Dr. Howe, and Mr. Hibbard. Dr. Sauveur spoke in high praise of the work of the Bureau of Standards and emphasized that if there is a method to make sound ingots, the ethical standpoint should not tolerate the use of unsound ingots for rolling rails. On the other hand in a discussion by Mr. F. W. Wood, it was stated that not all defects were eliminated by the Hadfield method, such as surface flaws and slag inclusions, so that it was still an open question how far rail failures could be avoided by the Hadfield process.

Other papers presented at this session were:

"Modern Gas-Power Blower Stations." By ARTHUR WEST, of the Bethlehem Steel Co. It was profusely illustrated by lantern slides and the possibility of an accurate measurement of the air (far superior to the use of Pitot tubes, etc.) was emphasized.

"Are the Deformation Lines in Manganese Steel Twins or Slip Bands?" By HENRY M. HOWE and ARTHUR G. LEVY. The evidence produced by the authors shows these lines to be slip bands, not twins.

"Structure and Hysteresis Loss in Medium-Carbon Steel." By F. C. LANGENBERG and R. G. WEBBER. In magnetic testing careful attention should be given to the previous history of heat treatment and the resulting internal structure of the metal undergoing test. A mere statement of its conditions as hardened or unhardened, annealed or tempered, is idle and often misleading. It would seem that a minimum hysteresis loss could be obtained by the combination of large grains with coarsely laminated pearlite.

"The Magari Iron-Ore Deposits, Cuba." By JAMES F. KEMP (illustrated by most interesting moving pictures).

American Potash

Simultaneously with the iron and steel session a session devoted to non-metallic minerals was held in an adjoining room. The question of possible American sources of potash was brought up in two papers.

Mr. CHARLES H. MACDOWELL, of Chicago, Ill., in his paper on "German and Other Sources of Potash Supply" referred to the inauguration of the manufacture of commercial fertilizers by Armour & Co. in 1894, his recommendations, and sketched the geology and mining of potash salts in Germany and elsewhere. As to the American possibilities he spoke as follows:

Some potash can be made as a by-product from other manufacturing industries. Practically no progress has been made in this direction in this country.

The sugar-beet tonnage in the United States totals 5,147,000 tons. Sugar-beet wastes from this tonnage could produce 30,900 tons of potassium carbonate, equal to 15,440 tons of pure potash.

Raw wool contains up to 20 per cent. potash salts. The wool clip of the United States weighs 298,000,000 lb. In wool scouring 7,450 tons of potassium carbonate or 4,470 tons of pure potash is washed out and lost. This could be largely recovered. Much raw wool from Australia and other countries is imported, and the potash from the handling of this wool could also be saved.

Potash from Cement Burning.—Many cements before clinkering contain small percentages of potash, say 0.1 to 0.25 per cent. In burning this is volatilized. While the percentage is small, the tonnage is so large it figures quite a production on paper.

Many experiments have been made to recover this volatilized potash. It has been worked out to a point where the physical part of the operation is a success. It consists of condensing the volatilized potash in chambers and dust collectors similar to the bag house used in smelters. Up to the present time, however, no cement manufacturer has produced potash as a by-product. Possibly the investment expense attached to its recovery figures against it. I have no data on this.

The industry is a possible source of a considerable tonnage of potash and in case of necessity can be utilized without any extensive changes in present methods of manufacture. Possibly cheaper recovery methods may be found.

At one time considerable carbonate of potash was derived from the ash from burning cotton hulls. These are now used for fodder, so no potash could be obtained from that source.

A few years ago tobacco stems were distilled destructively for nicotine and other products. The ash from this material contained high percentages of carbonate of potash. This method of handling has now been discontinued, but the potash in the ground tobacco stems is saved and used for fertilizing purposes.

This about exhausts the by-product possibilities as far as I know.

Hard-wood ashes and other ashes are gathered and used in fertilizing for their potash contents. City garbage contains appreciable percentages of potash. This garbage in many cities is recovered and used for fertilizing purposes.

The author then sketched the well known work of Government Bureaus, especially the Geological Survey, the Department of Agriculture, and the Bureau of Mines, and finally summed up as follows:

In by-product lines, the sugar manufacturer and the wool scourer might spend some money on solving their problem. The cement manufacturer could well afford to investigate potash manufacture from potash-bearing rocks in connection with cement manufacture.

If potash is to be produced in this country in quantity, some one must spend some money. There has been a noticeable reluctance on the part of American capitalists to finance serious research work, or prospecting by deep core drilling. To begin with, our mining laws and mineral withdrawal possibilities are discouraging. A German potash mine controls several thousand acres of mineral rights. The necessary capital investment would not be justified if this control was not legally obtainable. Potash mines with the necessary concentrating plants are expensive and a large acreage control is necessary. Deep core drilling or other development work on government lands by private individuals would not be justified during the present stage of development of the art of conservation as practiced by our legislators. A positive control of acreage must go with such preliminary work.

There is a large market for potash and the demand is growing. Possibly the lever of necessity may develop sufficient power to overcome the prevailing inertia. Up to now Searles Lake is the only nearby producer on the map.

Dr. WILLIAM B. PHILLIPS, Director of the Bureau of Economic Geology and Technology of the University of Texas, in a paper on an "Investigation of Sources of Potash in Texas" comes to the conclusion that the only hopeful outlook for the existence of workable beds of potash salts in Texas is in the direction indicated by Dr. J. A. Udden* in connection with the deep well at Spur, Dickens County, and in the almost wholly unknown region southeast of and bordering on New Mexico. Explorations in either of these areas would have to be in depth, with systematic chemical examination of cuttings and return waters.

White-Burning Clays

A paper by Dr. JOEL H. WATKINS, of Washington, D. C., on "White-Burning Clays of the Southern Appalachian States" dealt chiefly with the North Carolina, Virginia, and Georgia kaolins or china clays (residual); the South Carolina and Georgia kaolins or paper clays (sedimentary), and the Florida and Tennessee plastic kaolins or ball clays (sedimentary).

The economic aspects were sketched as follows:

In 1913 the United States produced white-burned products which had a total value of $31,443,450, and in the same year imported white-burned ware valued at $9,340,890. The total export of white ware from the United States in 1913 was valued at $149,281; thus showing that the total

*The Deep Well Boring at Spur, *Bulletin* of the Bureau of Economic Geology, University of Texas, No. 363.

value of the white-burned pottery products entered for consumption in the United States in 1913 was $40,635,059.

In 1913, the imports of kaolin or china clay into the United States amounted to 268,666 short tons, valued at $1,623,993, with an average value of $6.04 per ton. According to Parsons, "This kaolin displaced a like amount of domestic raw material which, if properly handled, has no superior." Against this, in the same year, only 197,276 short tons of kaolin and ball clay were produced in this country, which had a total value of $893,259 and an average value of $4.53 per ton. Thus it may be seen that our domestic production of white-burning clays is only equal to about two-thirds of our imports in quantity, and half of our imports in value.

In consideration of the wonderful reserves of high-grade clays in the territory described above, it would seem that the United States, instead of importing annually large amounts of clay, should produce enough to supply her own demands, and even be a competitor in foreign markets. There are several good reasons, however, for this great difference between imports and domestic production, but only reasons which are due to existing conditions, all of which can be easily overcome.

One of the principal objections made by American potters to domestic pottery clays is that the product is not uniform in character, or in other words, has not been properly prepared and classified before shipping. The potter justly demands a uniform product under guarantee, since the slightest variation in his ceramic mixture may cause the entire plant to be shut down until the irregularity is discovered and eliminated. Such variations may be of either chemical or physical character and may result in a lack of sufficient plasticity, a change in color on burning, a change in temperature at point of vitrification, a change in shrinkage, a tendency to warp and crack, and a failure to take the glaze.

To meet the requirements of the potter, therefore, the U. S. Bureau of Mines has wisely advocated a central depot where the output of a number of mines may be properly mixed and graded under the supervision of a trained ceramic chemist. Such a plant, if successfully engineered, should practically eliminate the present practice of mining to-day and shipping to-morrow, and should greatly stimulate the mining of kaolin by smaller operators. The output should demand a higher price than the clay is now bringing, and should capture the trade of our domestic potteries.

Such a plant, or holding company, could be operated successfully not only in the North Carolina residual kaolin district, but also in the South Carolina and Georgia sedimentary kaolin districts.

Another reason why American white clays are not more extensively used is because the clay mines, for the most part, are so remote from the manufacturing centers. Practically none of the white clays now being mined in the Southern Appalachian States are consumed in these States, and the bulk of the product has to be shipped by rail, more than 400 miles in the case of the North Carolina kaolins, more than 600 miles in the case of South Carolina and Georgia kaolins, and more than 700 miles in the case of Florida ball clays. If these clays were properly prepared, and could be sold under guarantee to the pottery plants, there is no doubt that the potter would get closer to the source of his raw materials.

Estimates submitted by a number of clay miners in the North Carolina field show that this material, under favorable conditions, can be produced at a cost ranging from $2 to $4 per ton, and has a selling price of from $8 to $9 per ton at the mines. In the South Carolina and Georgia field estimates were submitted showing a range in cost of production of from $1.50 to $3 per ton with a selling price of from $4 to $6 per ton. The writer was not able to obtain figures on the cost of production of Florida ball clay, but, considering the great thickness of the clay-bearing beds and the economical methods of mining, it would be reasonable to assume that the margins of profit should compare favorably with those of the North Carolina and Georgia mines.

In view of the large amount of white clay consumed by American manufacturers, and the growing demand for domestic clays, it would seem that the clay-mining business in this country is almost in its infancy. Also, a review of the distribution of the clay resources in the United States would point to the fact that America must in the future look to the South for her supply of domestic white-burning clays.

Mining and Milling

The morning session of Tuesday was devoted to mining and milling with the following program:

"Experiments on the Flow of Sand and Water Through Spigots." By R. H. Richards and Boyd Dudley, Jr.

"Development of the Butchart Riffle System at Morenci." By David Cole.

"The Boulder Batholith of Montana." By Paul Billingsley.

"The Main Mineral Zone of the Santa Eulalia District, Chihuahua." By Basil Prescott.

"Cloncurry Copper District, Queensland." By W. H. Corbould.

"Mining and Reduction of Quicksilver Ore at Oceanic Mine, Cambria, Cal." By C. A. Heberlein.

"Metallurgical Practice in Porcupine District." By Noel Cunningham.

"An Improved Form of Cam for Stamp Mills." By Arthur B. Foote.

"Method for the Determination of Gold and Silver in Cyanide Solutions." By L. W. Bahney.

Fuels

A technical session on fuels, under the auspices of the committee on petroleum and gas and the committee on coal and coke, was held in the afternoon of Tuesday. Captain Lucas presided.

The feature of the session—and a rather sensational feature—came at the end of the session in form of a paper, not on the printed program, by Dr. Snelling, of Pittsburgh, Pa., on "Synthetic Fuel Oil."

Gasoline from Synthetic Fuel Oil

Dr. Walter O. Snelling in his paper on "Synthetic Fuel Oil" sketched the results of an extended research carried out by him in following up a discovery which he made some five years ago. The gist of the very interesting paper is given in the following abstract:

When any hydrocarbon, such as kerosene oil, melted paraffin, vaseline, fuel oil, or any such material, is subjected to the treatment described it comes out after treatment a fluid having the characteristics of crude oil. Even water-white kerosene, after five minutes' treatment, comes out a dark green liquid by reflected light (dark red-brown by transmitted light), and which resembles ordinary Pennsylvania crude oil so perfectly that even an oil expert cannot pick out bottles of the manufactured crude when placed among bottles of natural crude.

This strong resemblance in appearance also extends to marked similarity in composition. When this "synthetic" crude is distilled, it yields gasoline, kerosene, gas oil, and lubricating oils, much as any ordinary crude oil would do.

By this process "synthetic" crude oils have now been made from such dissimilar materials as paraffin wax, kerosene, fuel oil, rod wax, bottom settlings, gas oil and many like substances. In every case the resulting "synthetic" crude oil has resembled natural crude oil and on distillation has been found to yield practically the same products.

Apparently this process discloses certain fundamental principles governing the transformation of hydrocarbon bodies such as has produced crude oil in nature. Apparently it also points out and discloses in a most interesting way the lines of work which must be followed to transform any hydrocarbon into any other hydrocarbon.

Much work has been done by others recently, in attempts to make gasoline from heavier oils. In general, all these processes have yielded light products in some ways suitable for use as gasoline, but having the disadvantage of a marked yellow color, and a bad odor, which could only be removed by treatment with acid, resulting in the loss of a large amount of material.

By the present process, we change any hydrocarbon into crude oil, and this crude oil gives about 15 per cent of absolutely colorless gasoline, without objectionable odor. The residue, after removing the gasoline, can be again put through the same process, when it will give more crude oil, and from this an additional 15 per cent of gasoline can be obtained.

This process can be repeated over and over, and in our experiments up to now we have obtained even from still residue (the very heavy residue remaining after petroleum refining) up to 55 per cent of colorless gasoline of excellent quality. From gas oil we have obtained 60 per cent of high grade gasoline, and from paraffin, 65 per cent of gasoline.

It should be emphasized that in every case the gasoline so produced has not been inferior, yellow, or bad smelling gasoline, but has been gasoline of the very highest grade, free from heavy ends (that is to say, free from products not of the proper gravity) and having an odor not one particle more objectionable than that of ordinary, carefully refined gasoline made in the usual way.

Apparatus and Process.—The present invention rests upon the discovery of the fact that, when any hydrocarbon is placed in a vessel of such size that the hydrocarbon occupies about three elevenths of the total volume, and is under these conditions heated to such temperature as brings about within the vessel a vapor pressure of 800 pounds per square inch, the hydrocarbon introduced into the vessel becomes changed into "synthetic" crude oil. For the best results a very small amount of a suitable catalyst (ordinary graphite, finely powdered nickel, copper, etc.) is added to the oil before the treatment described.

From the experiments made (representing some 2,000 tests) it appears evident that some very fundamental change is brought about in oil when treated in the manner described, and that this change is of so deep-seated an origin as to lead to the general rearrangement and regrouping of the molecules, and leading to the production of new chemical bodies very similar, if not absolutely identical, with the material present in natural crude oil.

It is not yet at all certain that this method is capable of practical application in oil refining, in view of the fact that the pressure employed is quite high for commercial work. On the other hand, the remarkable results obtained are of such nature as to lead without doubt to efforts being made to build apparatus of large size for such work, but the success of these experiments cannot now be foretold.

This research work has been conducted under the financial direction and assistance of Mr. John T. Milliken, of St. Louis, Mo., president of the Milliken Refining Co.

Non-Ferrous Metallurgy

An exceedingly interesting session, from beginning to end, was held on Wednesday morning, under the auspices of the Committee on Precious and Base Metals. Mr. CHARLES W. GOODALE presided during the first half of the session, Mr. E. P. MATHEWSON during the second half.

The first paper was presented by J. B. TYRRELL, of Toronto, Ontario, on "Gold-Bearing Gravels of Beauce County, Quebec," and illustrated by numerous lantern slides.

Chloridizing, Roasting and the Separation of Copper from Nickel

A paper by BOYD DUDLEY, Jr., of Pennsylvania State College, followed on "a study of the chloridizing roast and its application to the separation of copper from nickel." The investigation had been carried out at the suggestion of Professor H. O. Hofman at the Massachusetts Institute of Technology.

The purpose of the work was, first, to study some of the reactions that have been considered as a part of the mechanism of the chloridizing roast, and second, to study the conditions under which nickel oxide and copper oxide may be chloridized. While the production of chlorine gas by various reactions during the chloridizing roast may not be primarily useful in the chloridation of metal oxides and compounds, it nevertheless serves a useful purpose in preventing the dissociation and decomposition of chlorides once they have been formed; for example, the dissociation of cupric chloride into cuprous chloride and chlorine. Therefore it was thought that a study of some chlorine-producing reactions would prove of interest, and the first series of experiments dealt with this phase of the subject. The object of the latter part of the work was to show the possibility of treating heavy sulphide ores, such as those of Sudbury, Ontario, containing much iron and small amounts of copper and nickel, by chloridizing and removing the copper, leaving an iron-nickel oxide product suitable for smelting in the blast furnace for nickel-bearing pig iron. The chloridizing of the copper would, of course, be preceded by a roast for the removal of sulphur, the sulphur oxides being available for the manufacture of sulphuric acid, if under the local conditions this product would be of commercial value.

The author's laboratory experiments, while not permitting a conclusion as to the working of such a process on a large scale, prove the possibility of treating roasted pyritic ores, containing copper and nickel, by chloridizing the copper and leaching it from the iron and nickel oxides, leaving a product suitable to be smelted to nickel-bearing pig iron. The experiments also indicate the temperatures at which the roast should be conducted in order to secure the desired results.

Desilverization of Lead

A paper by F. C. NEWTON, of Maurer, N. J., followed on the "effect of Zn_3Ag_2 upon the desilverization of lead."

Refiners of lead by the Parkes process have always been solicitous of recovering the zinc used in the desilverization, and justly so, as the loss in zinc constitutes one of the heavy costs in this method of refining. Part of this loss is due to the absorption of zinc by lead, and in the present state of knowledge is not recoverable as metallic zinc. The remainder of the zinc, which finds its way into the precious-metal-bearing crust, is recoverable and naturally engages the operators' most exacting attention.

Careful elimination of the impurities in base bullion has enabled the refiner to produce a zinc crust better adapted to retorting, which reflects favorably in the zinc recovery; and to produce a richer crust, thereby lowering the zincking cost, as the increased efficiency of the zinc results in less of it being in circulation.

It is obvious that if the ratio of concentration be increased, a lessening of the amount of crust formed will ensue, throwing less work on the retorts and diminishing the amount of retort metal sent to the cupels, thus making an actual money saving in all these operations.

In the effort to obtain a rich crust, the metallurgist has increased the heat to a considerable degree, upon the assumption that at the higher temperature the zinc-silver alloy could be squeezed free from the adhering lead.

A further possibility for improvement suggested itself in the freezing-point curve of Prof. H. C. Carpenter, upon zinc and silver. Study of this curve disclosed the existence of a definite chemical compound, Zn_3Ag_2, with a freezing point of 665 deg. C., a promising compound for practical application.

In the experiment undertaken it was endeavored to force this compound into the crust, hoping thereby to obtain a higher concentration than formerly. It was recognized that in bringing a large kettle of lead to such a heat, more fuel would be used, the life of the kettle would perhaps be shorter, and other disadvantages would be experienced. As a commercial operation, the project would have to stand on its own feet, so the records were carefully kept to balance the advantages against the disadvantages.

The first experiment, however, showed such refinement unnecessary, as it was conclusively indicated that the melting point of the zinc-silver compound was so modified as to nullify its feasibility as a commercial factor. . . .

In every instance, the crust removed at the highest temperature, that is, just below the freezing point of Zn_3Ag_2, furnished the lowest retort metal. . . .

The tests clearly demonstrated the impracticability of removing the crust at a very high temperature. Further experiments were made to determine what beneficial result, if any, would be obtained by the greater heat. . . . In all cases where the greater heat was used for stirring and pressing, the dross and blue powder formed, especially the former, were far in excess of current practice. . . .

The conclusion to be drawn is, that as a commercial project, the slight increase in doré contents of the crust, which might be obtained from zincking at the greater heat, is more than counterbalanced by the attendant disadvantages. The current practice of to-day, dictated more or less by the question of fuel economy and better life of kettles, has been justified as a practical and efficient procedure from the standpoint of concentration. For comfort of operation, effect upon the men, etc., all arguments are in favor of zincking at a lower temperature.

The paper elicited quite some discussion in which Prof. H. O. Hofman, Prof. J. W. Richards and Mr. W. McA. Johnson participated.

A long descriptive paper by MANUEL EISSLER, of Paris, France, on "Copper Smelting in Japan," was then presented in abstract by Mr. Burr A. Robinson and briefly discussed by Dr. J. W. Richards.

Coal-Dust Fired Reverberatory Furnaces at Copper Cliff and Anaconda

Two very interesting papers on coal-dust fired reverberatory furnaces were then presented. Mr. David H.

Browne, of the International Nickel Company, spoke in his characteristic humorous and modest style on Copper Cliff practice. The paper by Mr. Louis V. Bender, of the Anaconda Copper Company, dealt with the practice at the Washoe Reduction Works.

Mr. David H. Browne, in his paper on "Coal-Dust Fired Reverberatory Furnaces of the Canadian Copper Company," gave first a historical sketch and noted the pioneer experiments of S. S. Sörensen at Highland Boy and Charles Shelby at Cananea. The mechanical difficulties encountered by them consisted chiefly of two things, viz.: the stoppage of flues with accumulations of ash, and interruptions and irregularities in the coal-dust feed. These were due to insufficient experience in the preparation and fine grinding of the coal, which is absolutely essential to success.

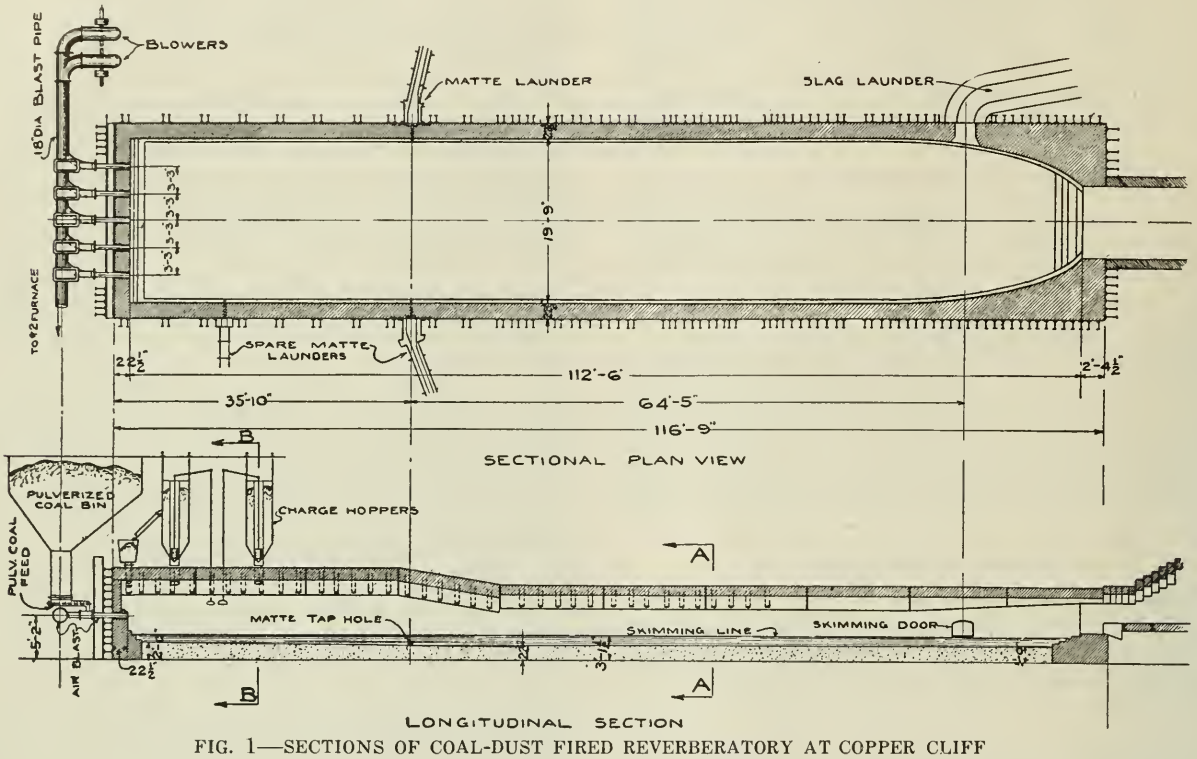

FIG. 1—SECTIONS OF COAL-DUST FIRED REVERBERATORY AT COPPER CLIFF

In April, 1910, the Canadian Copper Co. authorized construction, and work was begun at once. As the entire site of the proposed plant had to be raised 11 ft. above the yard level, and a large amount of rock cutting and filling was necessary on the hillside where the bins and approaches were planned, active construction of the reverberatory proper was slow, and operation did not commence until Dec. 23, 1911.

As built, the original furnaces were lined with basic brick, and the hearth was an inverted arch of magnesite. The furnaces went into operation before any proper means of drying flue dust was provided, and during the winter of 1911-12 a large amount of the charge, wet and frozen as it came from the piles, was shoveled in through the doors of the furnace. All the converter slag was poured in, at first through an opening in the roof, later by means of an iron chute through a door near the fire end, as scrap is charged in an open-hearth steel furnace.

The introduction of so much cold air and cold material prevented any satisfactory fuel ratio. During the first five months 21,406 tons of cold charge and 43,463 tons of converter slag were smelted with 9,609 tons of coal. This shows a ratio of 6.7 tons of total charge per ton of coal, but only 2.2 tons of cold charge per ton of coal. However, as the cold charge was wet and often frozen, better results probably could not be expected.

The combustion of fuel was satisfactory from the start,

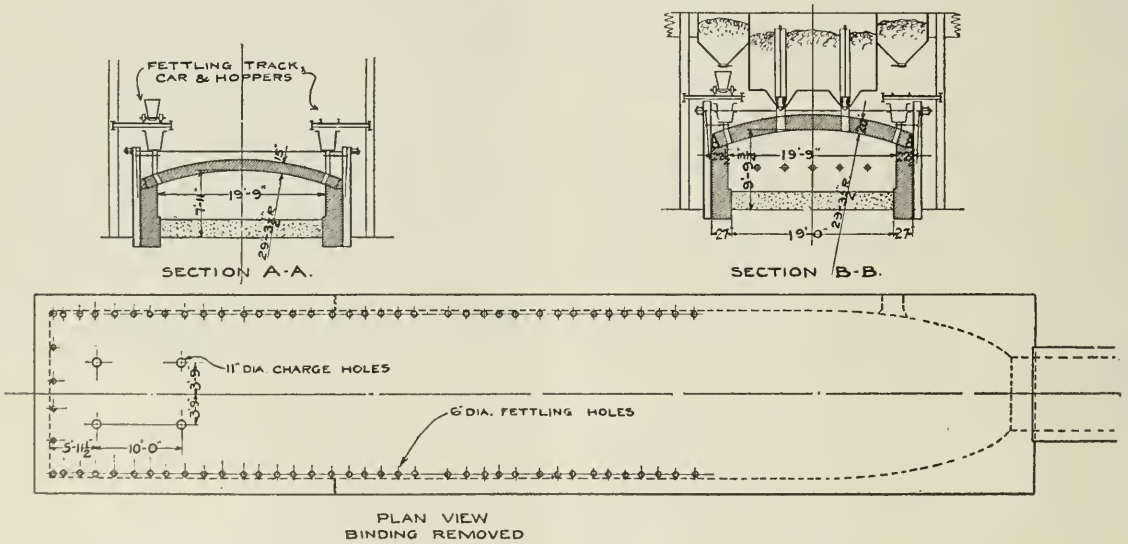

FIG. 2—DETAILS OF THE FURNACE SHOWN IN FIG. 1

no trouble being experienced either in grinding or burning the coal. The ash, while working on cold charges, choked and clogged the flue at the throat. This difficulty was not eliminated until later, when hot calcines were used and a larger tonnage was smelted. In general, the slower the furnace is worked the colder is the ash and the more it sticks and accumulates, while the faster it is driven the less does the ash hang back in the furnace. Under present conditions, with rapid smelting, the ash is a negligible factor.

In the summer of 1912, the roof and side walls were repaired and some facilities provided for drying the charge. In the winter of 1912, four Wedge furnaces were built to roast green-ore fines. These went into operation in March, 1913. At this date we ceased to send converter slag to the reverberatory furnaces, since with the opening of No. 3 mine the blast-furnace charge became more siliceous and slag could be used economically as a flux.

During this year very pronounced improvements were made by Mr. Agnew, then superintendent of the smelter, who with his foremen, Messrs. Kent, McAskill, and Mason, worked out and adapted to our use a modification of the Cananea system of side fettling. Long and shallow pockets were provided along the side walls, and through holes in the roof green-ore fines were fed to protect the sides. This naturally led to bricking up all the doors of the furnace, and the marked improvement which resulted from the exclusion of cold air and the insulation of the walls by a non-conducting and continuously renewed blanket of fines brought about the extension of this side-fettling system to take in almost the entire charge of calcines.

As the walls were thoroughly protected by the charge thus introduced, the use of basic brick in the walls and hearth was no longer necessary, and the next change, in October, 1913, was to the siliceous bottom and silica brick walls customary in Western smelters.

In 1914, the fuel ratio and furnace practice were steadily improving. The figures for the first three months in 1914, one reverberatory being in use, are given in table II.

In the summer of 1914, a change was made in grinding the ore fines for the Wedge furnace. The ore, which was previously too coarse to make a good calcination, was treated in ball mills, and screened, so that only about 14 per cent. remained on a 20-mesh screen, instead of the former 40 per cent. This finer-crushed ore cannot be produced in sufficient quantity to keep the furnace up to its full capacity. Furthermore, when the calcines dropped, on account of this finer grinding of the ore, from 13 per cent sulphur to 7 or 8 per cent, the production of slag increased and the production of matte fell off. These conditions, with shortage of calcines, militated against the high ratio of charge to fuel and in June, 1914, the fuel ratio was 5.35.

TABLE II. RESULTS OBTAINED AT COPPER CLIFF IN 1914

	January	February	March
Furnace days	31	28	31
Calcines, tons	10,020	9,460	10,860
Blast-furnace, flue dust, tons	906	922	847
Wedge-furnace, flue dust, tons	171	193	180
Converter slag	69	248	0
Green-ore fines and samples	1,731	1,326	2,308
Total charge	12,897	12,149	14,195
Coal	2,575	2,150	2,094
Charge per day	416	434	458
Coal per day	83	77	67
Ratio charge to fuel	5.0	5.65	6.77

The second part of Mr. Browne's paper deals with the design and construction of the Copper Cliff furnaces. These are shown in Figs. 1 and 2 on page 182.

The furnace is fed in a rather peculiar way. When the furnace was started almost all the charge was introduced through two charge hoppers near the fire end, as in the usual Western practice. The first hopper delivered through two openings 11 in. in diameter, 7 ft. 6 in. apart and 8 ft. from the outside of the fire wall. The second hopper delivered through two similar openings 18 ft. from the fire wall.

At present almost all the charge is introduced through hoppers along the side walls. Directly over the side walls, at the fire end of the furnace, large bins are provided, which discharge into small bottom-dump cars. These cars run on 24-in. tracks which are supported from overhead. Under these tracks a long trough extends down each side of the furnace just above the side walls. These troughs are filled from the cars on the track above them. Each trough has openings in the bottom, 2 ft. apart, which openings communicate by a slide gate with 6-in. iron pipes. These pipes pass into holes drilled in the roof bricks which allow the charge introduced through these openings to slide down on the side walls, over which this charge forms an almost continuous blanket. As there are no doors on the furnace, and as the 6-in. pipes are clayed into the openings in the roof, it follows that no air is introduced into the furnace except what is purposely introduced at the fire end.

These pipes form a continuous line of charging holes, which extend the entire length of the furnace. The charge on the side opposite the slag door is fed all the way to the throat. On the slag side it is fed along as far as the slag door and no farther, as the cold air coming in while skimming cools the wall from the skim door to the throat and obviates the necessity of charging beyond this point. Six similar openings are used on the fire wall. . . .

The coal dust is introduced through five pipes, 5 in. in diameter. One of these pipes is on the center line of the furnace; the others are in horizontal line with it at distances of 3 ft. 3 in. from center to center. These pipes are 5 ft. 2 in. above the bottom of the sand hearth, or 3 ft. 2 in. above the top of this hearth. They are about 2 ft. above the skimming line of the charge and the central pipe is about 4 ft. 8 in. below the highest point of the roof.

The coal used in firing is a good quality of slack. Analysis of one lot showed: Volatile matter, 34.70; fixed carbon, 55.40; ash, 9.45; sulphur, 1.30; moisture, 4.31 per cent.

This coal has a thermal value of about 13,500 B.t.u. per pound. It is about ¾ in. and under in size and contains about 7 per cent. moisture. It is dried in a Ruggles-Coles drier, 70 in. in diameter and 35 ft. long. One ton of coal burned on the grate dries 40 to 50 tons of slack coal to about 5 per cent moisture, which falls to 2.4 per cent. moisture after grinding. About 10 tons of slack is dried per hour of running time. The coal is ground in Raymond impact mills. About 95 per cent passes a 100-mesh and 80 per cent passes a 200-mesh screen.

The pulverized coal is sucked by a fan to separators above the roof of the drier building, and slides down into a screw conveyor which delivers it into bins at the fire end of the reverberatory. The dust is fed from these bins by Sturtevant automatic-feed screw conveyors, one for each nozzle, the speed of which can be regulated. These screws carry the dust forward and drop it into the air nozzles about 2 ft. from the point where the nozzles enter the furnace. Any coal-delivery pipe can be closed off by a slide gate, and any screw conveyor can be stopped by disconnecting the bevel gears attached thereto. In this way any desired number of the five burners can be run, and at any desired speed within wide limits. The amount of air delivered to each nozzle can be varied at will or cut off entirely.

As a rule the five burners are in operation. Each delivers about 13.5 tons of coal dust a day or about 19 lb. of coal per minute to the furnace. The total coal blown in is about 67 tons a day.

The dust drops from the conveyors into the air pipes which carry it forward into the furnace. The air is supplied by a 4-ft. Sturtevant fan, running at about 1300 to 1400 r.p.m. The air supplied by this fan is insufficient for the combustion of the fuel. Openings are left in the end wall between the coal burners. These openings are stopped by loose bricks, so that the amount of air is readily controlled. The draft at the fire wall is about 0.25 in. of water and at the throat it has a maximum of about 1.2 in. The combustion is very good. One test made for 10 days (Jan. 9 to 19, 1914) showed the following averages:

Coal consumption, tons in 24 hr.	69.7
Gas temperature at throat, degrees centigrade	922
SO_2 and CO_2, per cent.	12.3
Oxygen, per cent.	6.5
SO_3, per cent.	1.14

During this test the average charge was 409 tons in 24 hr. This shows a ratio of 5.9 parts charge to 1 part coal, but much higher ratios have been attained. The average for March, 1914, was 6.84. This coal ratio depends largely upon the composition of the charge and the analysis of the slag produced.

A criticism might be made of the low temperature of the gases at the throat, 922 deg. C. The usual practise in Western smelters is to carry a temperature of 1200 deg. to 1300 deg. at this point, and it might be thought that this low temperature indicated inefficient firing. The fact is that the heat of combustion is utilized in smelting ore along the side walls and consequently the escaping gases, having done more work than is usually the case, are relatively cold. The function of a reverberatory furnace is to melt ore, and not to raise steam, and for this reason the more heat that is absorbed from the coal gases in the furnace, the more efficient the operation and the cooler the escaping gases.

The ash from this coal causes very little trouble in operating. A small amount settles on the slag, but as this slag is high in iron it is not an undesirable feature. A small amount also settles in the flue and a few hundred pounds may stick around the throat. The ash, where exposed to high heat, forms a very light pumice-like fragile mass. The throat is cleaned out daily by opening the door under the flue. During this cleaning the firing is maintained as usual.

The great advantage of coal-dust firing is the absence of the usual breaks in the temperature curve due to grating or cleaning the hearth, and as a consequence a greatly increased tonnage and fuel ratio. The operation of firing, being purely mechanical, comes under the immediate and direct control of the furnace foreman and responds instantly to his regulation. In addition to this, the peculiar method of feeding by almost continuous side charging obviates the breaks in the temperature curve due to charging or ordinary fettling. For these two reasons the chart of the temperature shows an almost horizontal line, rising or falling in almost exact concordance with the speed of the coal-feeding device.

The maximum bath of matte and slag is 22 in. deep. A constant bath of 8 in. of matte is carried. This matte lies 6 in. below the skimming plate, so that after skimming there are 6 in. of slag and 8 in. of matte left in the furnace, making a total minimum depth of 14 in. The skimming door is banked up 8 in. with sand, so that just before skimming the slag is 14 in. deep. As the charge along the side walls occupies a great deal of room there is never at any time more than 40 or 50 tons of slag in the furnace.

In rebuilding this reverberatory, or in designing a new plant, the hearth should be widened to provide for a larger body of matte, which experience has shown to be necessary. As this method of burning coal and of admitting the charge into the furnace bids fair to come into general use it is to be expected that many changes, both in construction and operation, will be introduced. My belief is that reverberatory smelting along these lines will become cheaper than blast-furnace smelting and that a wider range of ores can be used in such a furnace than in the old-style coal or oil-fuel furnaces.

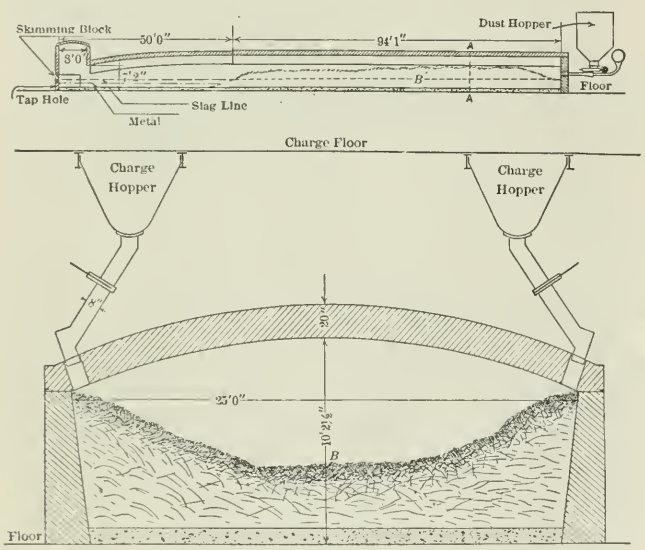

FIG. 3—LONGITUDINAL SECTION AND CROSS-SECTION ALONG LINE AA OF ANACONDA COAL-DUST FIRED REVERBERATORY

Mr. Louis V. Bender's paper deals with "coal-dust fired reverberatories at the Washoe Reduction Works." He describes how after investigating Mr. Browne's work at Copper Cliff, the Washoe Reduction Works decided to experiment with coal dust as fuel in their reverberatories and changed their reverberatory furnace No. 8 to the use of this fuel in June, 1894.

The charging is done on either side of the furnace from longitudinal hoppers, extending a distance of 74 ft. from the back end of the furnace. Leading from the hoppers into the furnace are 6-in. pipes, spaced 19¼ in. apart, through which the charge is intermittently dropped. The charge is kept well above the slag line at all times; in this way the side walls are protected and no fettling is needed on this portion of the furnace. The remainder of the furnace requires fettling. . . .

Conditions which are imperative in order to obtain successful results in coal-dust firing are:

1. The coal, before pulverizing must be well dried, down to 1 cent. or less of moisture. This makes it pulverize better and burn more freely. Nothing is lost in drying it separately, as all the moisture must be evaporated before coal (or any other fuel) will burn, and higher efficiency is obtained when the moisture is driven off before using. The furnace itself is the most expensive place in which to dry the coal, as the effectiveness of the whole fire is lowered by the presence of moisture.

2. The coal must be finely pulverized. The increased surface has a direct bearing upon the efficiency obtained in coal-dust firing. It is well to recognize what this increase is. C. D. Demond, Chief Testing Engineer at the Washoe Reduction Works, says: "The approximate diameter of a 1-lb. lump of bituminous coal is 3 in., and its total surface one-quarter of a square foot, while 1 lb. of coal ground so that 95 per cent. will pass through a 100-mesh sieve and 82 per cent. through a 200-mesh sieve has a total surface of 8000 sq. ft., more or less, depending upon the physical characteristics of the coal, or 32,000 times the area of the single lump."

These figures show that with finer grinding an enormous increase in surface is obtained, and, consequently, an increase in thermal efficiency. At Anaconda the grinding is done so that from 93 to 97 per cent. will pass through 100 mesh and 79 to 82 per cent. through 200 mesh. . . . The standard of approximately 85 per cent through 200 mesh and 95 per cent through 100 mesh is a practicable commercial standard and should be maintained.

3. The delivery of the coal and air to the furnace must be controlled so that the proper quantities of each may be secured. Undoubtedly, the proper method of firing pulverized coal is to admit with the fuel the exact quantity of air required for the results to be attained, and to maintain this relationship as long as results wished for are obtained. We know that in order to get the best heat efficiency from fuel a certain amount of air must be provided for combustion. Any air in excess of these requirements dilutes the gases and lowers the temperature; and insufficient air will burn part of the fuel to CO_2 and part of it to CO, which means incomplete combustion.

4. The coal must contain enough volatile combustible matter to give the required combustion. In cement work coal containing as low as 22 per cent. V.C.M. has been used. James Lord, of the American Iron & Steel Co., recommends 30 per cent as a minimum.

5. The furnace must be properly proportioned, properly equipped, and in good condition.

6. Provision must be made for taking care of the ash formed.

The powdered-fuel equipment at Anaconda is then described and the advantages of powdered-fuel firing are summed up as follows:

1. An increase in tonnage, which makes it possible to smelt the necessary tonnages with fewer furnaces.

2. The efficiency of this method is much greater than that of burning coal on grates. In burning coal on grates, there is a loss in transferring to the hearth the heat generated in the fire box. This does not occur in coal-dust firing, where the combustion occurs over the hearth itself. Another point is that none of the heat is lost in gratings from the fire box. In our practice of grate firing, this loss amounts to something like 10 per cent of the fuel values. The efficiency is greater, due to a uniform temperature being maintained. There are no fluctuations in temperature due to firing cold fuel or to grate cleaning, or to the personal equation of the men firing the furnace.

The superintendent before leaving his work can adjust the feeding of the coal, and by securing this adjustment with a padlock he can be certain that a definite amount of coal will be burned during his absence. If, for any reason, the furnace men need to shut off the burners, they can do so by releasing a clutch; when this clutch is re-engaged, the burner resumes firing at the original adjustment.

3. Higher temperatures than usual can be produced and maintained because the quantity of coal burned can be easily increased, and also, because there is less excess air to be heated. In grate firing 100 per cent excess air is used, while in dust firing only 25 per cent excess air is required. There being a smaller volume of gases, they will remain longer in the furnace, and, consequently, give up more heat to the charge.

4. Less draft is required because there is no bed of coal through which air is drawn. This is an advantage in that less cold air is drawn into the furnace through the side walls.

Details are given of the results of tests made in September, 1914. The fuel ratio was 7.19 (excluding drier coal) and 7.08 (including drier coal). The ash gave very little trouble.

"The efficiency of this method of firing is improving

so rapidly that a paper is almost out of date before it can be read. New records for tonnage and fuel ratio are made almost every day. The average tonnage per day for the past week was 542.7, with a fuel ratio of 7.50."

The paper by R. E. H. POMEROY, of McGill, Nev., was next presented in abstract, dealing with the "reverbaratory smelting practice of the Nevada Consolidated Copper Co." California crude oil is used as fuel. The results are excellent. A longer abstract of this interesting paper is reserved for our next issue.

These papers were discussed together and the discussion was lively and extended. Mr. Mathewson read from a telegram the latest results achieved in Anaconda.

A communicated discussion described the results obtained at the smelter at Garfield, Utah.

Mr. J. B. Herreshoff paid a fine tribute to the bigness of Western smelters, Western men, and Western open-heartedness and gave details of a big reverberatory (with grate firing) in an Eastern copper plant.

Mr. Klepetko suggested that the excellent results obtained were due perhaps more to the charging on the sides than to the use of pulverized coal. While the charging on the side is an important factor, Dr. J. W. Richards pointed out that there is no getting away from the fact that in a grate-fired furnace 25 per cent of the calorific value of the fuel is lost from the fire place; this loss is wiped out by the use of powdered coal.

Mr. Mathewson stated that with their big new reverberatory the expectations were to realize a tonnage of 750 per day with a fuel ratio of 7½. He also exhibited a brick made from the flotation tailings of slimes at Anaconda (70 per cent silicon, 21 or 22 alumina, 1 sulphur, 0.8 lime) and predicted a big future for this brick.

Mr. D. H. Browne emphasized again in his modest way that most of the Copper Cliff success had been due to the work of "the boys" at the smelter.

In the afternoon of Wednesday there was a session devoted to papers on mining and the application of electricity in mines. On the same afternoon a visit was paid by members and their ladies to the Art Galleries of Senator W. A. Clark.

The seventeenth annual meeting of the **Canadian Mining Institute** will be held at Toronto, March 3, 4 and 5, 1915. Headquarters will be at the King Edward Hotel. The provisional program contains some excellent papers relating to mining and metallurgy in Canada.

The **Calumet & Hecla Mining Co.** has just completed the installation of 12 large Hardinge mills in its new White Pine concentrator. Three Hardinge ball mills of the largest size are to be installed in the plant of Moose Mountain, Ltd., at Sellwood, Ontario, Canada.

Messrs. **Chalmers & Williams**, of Chicago Heights, Ill., announce that they have taken over the exclusive rights of manufacture and sale of the Symons disc crushers, Symons fine reduction disc crushers and Symons pulsating screen.

The **Snyder Electric Furnace Company** is the new name of what was formerly the Metallurgic Engineering Company. The business of the company is largely devoted to the building of the Snyder type of electric furnace. Mr. F. T. Snyder is the president, Mr. Carl H. Book, vice-president; Mr. W. K. Booth, secretary, and Mr. F. E. Berggren, treasurer of the company. The office is at 53 West Jackson Boulevard, Chicago, Ill.

The **American Electrochemical Society** will hold its spring meeting from Thursday to Saturday, April 22 to 24, at Atlantic City, N. J.

Recent Chemical and Metallurgical Patents

Iron and Steel

Sintering Apparatus.—Improvements in apparatus for sintering fine iron ore are embodied in a patent granted to STEPHEN A. KROM, of Birmingham, Ala. The invention relates to sintering apparatus of the pan type, in which a charge of ore is ignited and sintered and then dumped by tilting the pan. The object of the improvements is to secure equalization of draft and uniform ignition, and to prevent the accumulation in the bottom of the pan of fine material falling through the grate bars. To this end the pan is constructed with a conical bottom. From the apex of the cone a connection is made by pipe with a tank or receiver; the exhaust fan is connected with the pipe between receiver and sintering pan. The pan is fitted with an air-tight cover, through which the gas burner tubes extend over the surface of the charge from a main or header outside. By this construction even ignition is secured over the surface of the charge, and the suction is uniform by reason of the fact that it is taken from the apex of the cone bottom. Fine particles of ore falling through the grate are directed by the conical bottom and connecting pipe to the tank or receiver. (1,125,125, Jan. 19, 1915.)

Iron-Boron-Carbon-Copper Alloy.—An alloy that is practically non-corrosive and which can be rolled and machined without being annealed, is patented by EDWARD D. GLEASON, of New York City, the patent being assigned to the Neu-Metals and Process Company, of Long Island City, N. Y. The boron is first incorporated in the copper, the boron being in excess of the quantity that will combine with copper, and this boron-copper is added to low-carbon steel. (1,126,629, Jan. 26, 1915.)

Gold and Silver

Slime Filter.—An improvement in vacuum filters or pans of the tray type is patented by WALTER E. TRENT, of Reno, Nev. A transverse vertical sectional view of the apparatus is shown in Fig. 1. It consists of two oblong trays 1 and 2, supported apart as shown and adapted to be turned on a trunnion 8′. Suitable connection is made between the filter frames resting in the pans and a source of vacuum. The filter frames consist of pipes 16 and 16′ perforated as shown in 16². The slime to be treated is delivered to hoppers 11 and thence by pipes which are extending over the surface of the filters. Water spray pipes 20 and 20′ are placed as shown. In operation the slime is delivered to the filters and the liquid drawn from the solids, leaving the latter as a cake on the filter surface. Water is then admitted through the spray pipes to lubricate the filter surface so that the cake will slip from the filter when the apparatus is tilted. (1,125,769, Jan. 19, 1915.)

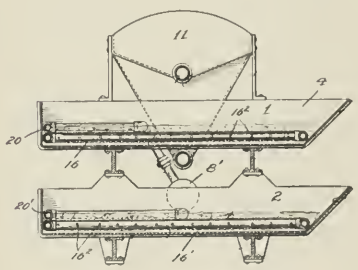

FIG. 1—SLIME FILTER

Precipitant for Gold and Silver in Cyanide Solutions.—A brittle alloy of zinc and sodium, or zinc and any other alkali or alkaline earth metal which will produce brittleness in the resulting alloy, is patented by G. HOWELL CLEVENGER, of Palo Alto, Cal. The patent is assigned to the Merrill Metallurgical Co., of San Francisco, Cal. The alloy thus produced by adding about three per cent sodium to zinc, can be comminuted and used in place of the other forms of zinc

now common in the precipitation of precious metals from cyanide solutions. (1,123,685, Jan. 5, 1915.)

Method of Precipitating Cyanide Solutions.—A method of combining the operations of precipitating and filtering cyanide solutions containing precious metals, is patented by Louis D. Mills, of Johannesburg, Transvaal, South Africa. The patent is assigned to the Merrill Metallurgical Co., of San Francisco, Cal. The apparatus and method is illustrated in Fig. 2. A tank 1 contains filter leaves 2 disposed vertically in the usual manner and having connections with a pump 4 or other means for exhausting the interior of the leaves. The receptacle 14 is for pregnant solution and the apparatus 13 is a feeder for zinc dust or other mobile precipitant to be mixed with the solution. The solution and precipitant are both delivered into the hopper 9 which is mounted on a revolving shaft 8. From the hopper the mixed solution and precipitant flow through pipes 6 having apertures 7. These pipes also revolve with the shaft and hopper, and provide means for uniform distribution of the mixture above the filter leaves. For the purpose of circulating the solution and precipitant and preventing the accumulation of solid matter in the bottom of the tank, a series of rakes 22 is mounted at the bottom of the shaft 8, similar to the mechanism of a Dorr thickener, and in the course of their revolutions they move any solids toward the central discharge point 20, whence solution is pumped back to the hopper as shown. In operation, the exhaustion of the leaves by the pump 4 causes a cake of precipitate to form on the leaves, and the solution passing through this cake is subjected to precipitating action. When it is desired to recover the cake, the supply of fresh solution is shut off, the pump 4 stopped and the precipitate sluiced from the leaves. It can then be removed from the tank by the pump 11 and pipe 23. (1,123,778, Jan. 5, 1915.)

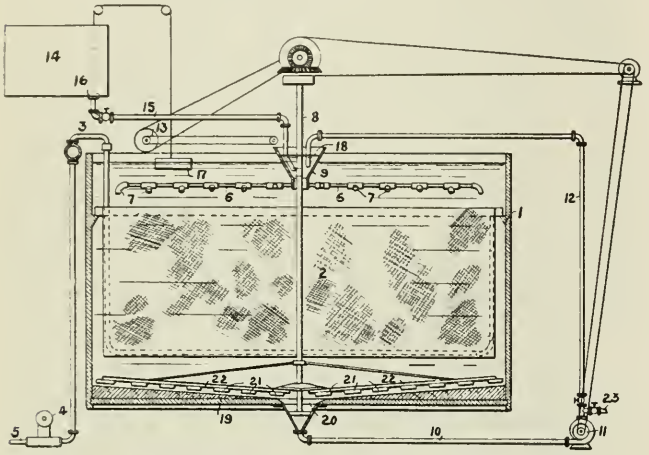

FIG. 2—PRECIPITATING APPARATUS

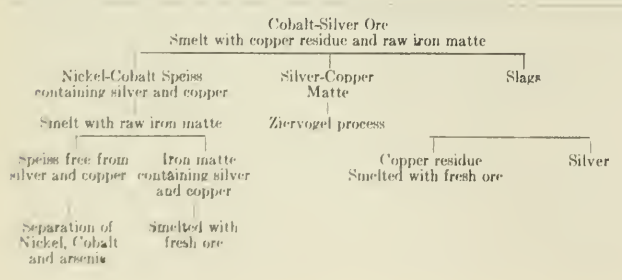
Treatment of Cobalt-Silver Ores.—According to a process patented by William Phillips, of Swansea, Wales, cobalt-silver ores can be treated for the recovery of silver, nickel, cobalt, copper and arsenic. An outline of the process is given below.



Cobalt-Silver Ore
Smelt with copper residue and raw iron matte
Nickel-Cobalt Speiss containing silver and copper
Silver-Copper Matte
Slags
Smelt with raw iron matte
Ziervogel process
Speiss free from silver and copper
Iron matte containing silver and copper
Copper residue Smelted with fresh ore
Silver
Separation of Nickel, Cobalt and arsenic
Smelted with fresh ore

The first step is performed in a reverberatory furnace. About 82 per cent of the silver in the ore passes into the copper matte, and about 17 per cent into the speiss. Also about 16 per cent of the copper passes into the speiss. The silver-copper matte will contain between 2000 and 3000 oz. silver per ton and about 25 per cent copper. The silver is extracted by the Ziervogel process.

The first raw speiss is smelted in a reverberatory with raw iron matte, the operation being repeated several times. About 60 per cent of the silver goes into the iron matte in the first smelting. (1,127,506, Feb. 9, 1915.)

Copper and Tin

Electrolysis of Copper Solutions.—A process of electrolyzing copper solutions containing iron, without first reducing the iron to the ferrous state, is patented by N. V. Hybinette, of Christiania, Norway. He makes use of a cell containing a diaphragm separating the anode from the cathode. A continuous flow of solution is maintained on the anode side only, and the solution on the cathode side is effected only by such changes as can be transmitted by diffusion. The solution on both sides of the diaphragm may, in the beginning of operations, contain 20 g. of iron as ferrous sulphate, 40 g. iron as ferric sulphate, 40 g. copper as sulphate and 50 g. free acid. When the current is applied the iron in the cathode is reduced and copper begins to plate. If then the solution on the anode side is continuously circulated so as to maintain a uniform composition, the solution on the cathode side will automatically adjust itself to contain say, 55 g. ferrous iron and 20 g. copper. The inventor states that "without any apparent reason copper is entering the cathode compartment, while ferric salts do not enter and the electric energy is therefore used to deposit copper and not to reduce ferric salts." With a concentration of solution mentioned, he uses a density of 10 amperes per sq. ft., and obtains an efficiency of nearly 90 per cent. The voltage is approximately 3. In Fig. 3 is shown a cell for this work; B is the anode and C the cathode, the latter being enclosed in a diaphragm formed of a double-walled leaden screen D secured to a wooden frame K which is filled with asbestos or other porous material. The electrolyte flows in at F and out at G. (1,123,299, Jan. 5, 1915.)

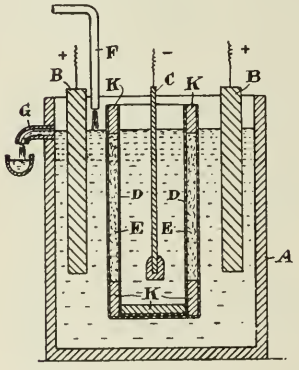


FIG. 3—ELECTROLYTIC CELL

Purification of Copper.—A method of producing pure copper for electric purposes and for the manufacture of copper-clad metals is patented by Wm. M. Page, of Philadelphia, and Wirt Tassin, of Chester, Pa. It consists in deoxidizing molten copper at a high temperature by the addition of iron or steel, and later removing the excess of iron by covering the bath with carbon. This has the effect of blanketing the bath with oxides of carbon, both of which are oxidizing to iron but not to copper. The copper, after purification, is cast under conditions which preclude oxidation during the pour. In making copper-clad metal, the metal to be treated is prepared in a special manner and then dipped in the copper. (1,125,164, Jan. 19, 1915.)

Sulphatizing Roast for Copper Ores.—The conversion of copper sulphide into sulphate for purposes of leaching the soluble copper salt, is usually accom-

plished by roasting under certain conditions. According to a patented process of A. D. CARMICHAEL, of West Norfolk, Va., this sulphatizing can be accomplished by first heating the ore out of contact with the air to a temperature between 500 deg. and 700 deg. C., at which temperature the formation of iron sulphate will be avoided, and then exposing the heated ore to air, preferably heated. One advantage claimed is the production of more concentrated sulphurous acid gas, suitable for making sulphuric acid, than can be made by ordinary roasting processes on low-sulphur ores. Other advantages lie in forming no iron sulphate, or in rendering iron insoluble. (1,124,696, Jan. 12, 1915.)

Copper Converter.—An improved form of converter is patented by HERBERT HAAS, of San Francisco, Cal., having for its object the converting of mattes into blister copper continuously instead of intermittently as in present methods. As shown in Fig. 4, the converter consists of a shell lined with magnesite brick. The bottom comprises a central inverted cone or bell portion and a depressed annular portion. In the center of the cone is the tuyere block in which are formed tuyeres that are directed upwardly, outwardly and preferably tangentially. A tap-hole is placed at the level of the depressed annular portion for the removal of molten copper, and an upper tap-hole for the removal of slag. The tuyeres are greater in number, but of smaller cross-section than those in ordinary converters, thus affording more efficient use of air. The function of the depressed annular portion is to store reduced, molten copper and remove it from the action of the blast. (1,123,868, Jan. 5, 1915.)

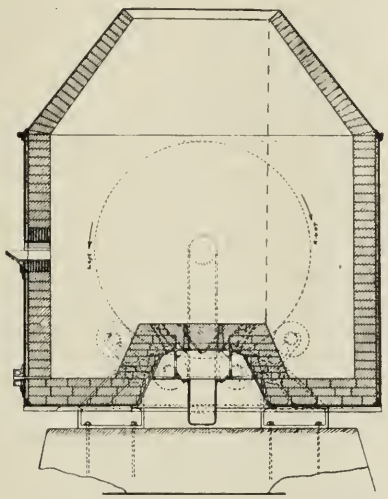

FIG. 4—COPPER CONVERTER

Electrolytic Refining of Tin.—A process of electrolytically refining tin, patented by GEORGES MICHAUD and EUGENE DELASSON, of Montreuil, France, consists in passing a current from an anode of impure tin to a cathode through an electrolyte composed of 100 parts by weight of tin protochloride, 10 of sulphuric acid, 1 of madnesium chloride and 1 of boric acid, mixed with water to make a solution of 20 deg. Baume. The cathodes are formed by copper plates arranged on edge, and upon the upper edges of which the tin is deposited in non-adhesive form and mechanically removed. The homogeneity of the electrolyte is maintained by circulating it through a trough containing tin waste of any kind. The inventors claim that the process will produce 2.22 grs. of chemically pure tin per ampere hour in a more economical manner than with arrangements ordinarily used. (1,124,315, Jan. 12, 1915.)

Uranium, Vanadium and Radium

Treatment of Carnotite Ores.—A method for treating complex carnotite ores for the recovery of uranium, vanadium and radium is patented by CHARLES W. DANFORTH, of Youngstown, O.; WILLIAM P. SAMUELS, of New Castle, Pa., and WILLIAM T. MARTERSTECK, of Youngstown, O. The method consists in giving the ore an oxidizing roast, then adding sulphuric acid to precipitate barium and radium into the residue and dissolve uranium and vanadium. The solution is separated by filtration. The ore is ground to about 40-mesh and roasted in an oxidizing atmosphere at a temperature of 1100 deg. F. for about an hour. The addition of sulphuric acid is said to dissolve about 90 per cent of the vanadium and all the uranium, leaving the barium and radium as sulphates with the sandy residue. To recover the radium, the residue is washed free from acid and treated with a solution of caustic soda and sodium carbonate. This changes the barium and radium compounds into carbonates. The mixture is then filtered and washed, leaving the barium and radium still with the residue. The addition of hydrochloric acid then dissolves the barium and radium. The solution is removed and precipitated with sulphuric acid, the sulphates separated and again converted into chlorides, after which the radium is concentrated by crystallization.

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Magnetic Habits of Alloy Steels.—There is a certain relationship between the magnetic and physical characteristics of steel and its alloys, distinct similarity between their magnetic and physical behavior. Dr. J. A. MATHEWS, in a very interesting paper (*Proceedings*, American Society for Testing Materials, Vol. XIV, 1914) brings out some interesting new relations and remarks justly that the fascination of magnetic investigations lies in the frequency of unexpected results. He suggests a new magnetic unit of magnetic hardness B_r/H_c; that is, the ratio between residual density and coercive force is used to indicate magnetic hardness in a way similar to the use of μ to indicate permeability. Dr. Mathews discusses the relation between hardness as measured by the Brinnel and Shore methods and magnetic hardness as indicated by B_r/H_r. In hardened alloy steels the magnetic properties vary with the cross-section, but in some cases, the magnetic hardness increases as the section increases while in other cases the reverse is true, and in some alloy steels either condition may be had, depending upon the manner of quenching. Many alloy steels give lower induction, lower residual density and higher coercive force when quenched in oil than when quenched in water; the corresponding physical hardness test showing, as would be expected, that the water quenching confers the greater hardness. The effect of drawing the temper of hardened alloy steels is discussed and it is shown that for equal drawing temperatures the magnetic properties of oil-hardened pieces are most affected, while as to the physical hardness the water-hardened pieces are affected to the greater degree.

Gold and Silver

Metallurgical Practice in the Porcupine District.—In a paper presented at the New York meeting of the A. I. M. E. last month, Mr. NOEL CUNNINGHAM, formerly mill superintendent for the Hollinger Gold Mines, Ltd., discusses the metallurgical technology of Porcupine district ores. His notes supplement milling articles of a descriptive nature, such as appeared in METALLURGICAL AND CHEMICAL ENGINEERING in September and October 1914.

There is no oxidized ore in the district. The precious-metal content is about in the proportion of 85 of gold to 15 of silver by weight. Two classes of ore are distinguished: *Class A*, which is pure quartz with inclusions of schist, containing free gold which is 60 per cent. to 85 per cent. free-milling, spongy and readily soluble in cyanide solution. *Class B*, which is an iron

silicate schist, contains 4 per cent. to 5 per cent. pyrite. This ore produces in grinding a comparatively large amount of non-crystalline slime which is quick settling. The gold is free, but so fine that it will neither amalgamate nor pan; it is disseminated through the rock and not chiefly associated with the pyrite.

After giving a brief outline of the mills, past and present, in the Porcupine district, the author analyzes milling practice and makes some comparisons of methods. In regard to stamps vs. ball mills as crushers preliminary to tube-milling, the author is of the opinion that ball mills are preferable on Porcupine ore. On the subject of stamping in water and amalgamating vs. stamping in solution without amalgamation, the author compares Dome and Hollinger practice, respectively:

"The advantages claimed for stamping in water and amalgamating are a better recovery of the coarse free gold and the saving in treatment cost, due to a smaller amount of solution to precipitate and a smaller amount of precipitate to handle. At first sight it would also appear that a saving in dissolved losses from the filters would be made, owing to the smaller amount of gold in solution going to the filters.

"While at the Hollinger there is a smaller percentage of amalgamable gold in the mill heads than at the Dome, on the other hand, the coarse free gold per ton of ore in the mill heads is about the same due to the fact that the head assay is nearly triple that of the Dome. Hence, if amalgamation is necessary in order to assure the dissolution of coarse gold in cyanide solution, difficulty from this source should be experienced at the Hollinger, where crushing is in solution with no amalgamation.

"This is not the case, however; all the coarse gold goes into solution in the classifier-tube mill closed circuit. This is proved by two facts in connection with the Hollinger operations. Table concentration after fine grinding is practiced at the Hollinger, and any coarse free gold passing the tube mill-classifier closed circuit would be caught on the tables. No coarse gold is present in table concentrates, however, no color of free gold ever showing on the tables; also practically no amalgam was produced (under 1 per cent. of the total values recovered) during six months, pan-amalgamation of concentrates from the tables.

"Facts also indicate that crushing in solution without amalgamation has the best of the argument in regard to amount of solution precipitated and dissolved gold mechanically lost. With the head assay at the Hollinger about three times as high, the precipitation ratio is only about twice that at the Dome, and the mechanical loss of dissolved gold and cyanide only about one-half. Nor is any saving in dissolved losses or treatment cost proved in favor of crushing in water followed by amalgamating. On the other hand, there are added to the treatment cost, (1) cost of amalgamation, (2) cost of increased cyanide consumption due to 'waste' solution precipitated and thrown away, and (3), in winter, the cost of heating to mill temperature the quantity of water—equaling several times the weight of ore treated and introduced at nearly a freezing temperature—to replace the water and waste solution discharged with the tailing, which would not be necessary if crushing were done in solution. The loss of gold left in 'waste' solution after precipitation must also be added to the cost.

"In comparing Dome and Hollinger metallurgical practice, it is only fair to state that since the Dome ore is harder and more compact, the gold may be less spongy and therefore less amenable to cyanidation. The only deduction which can be drawn from the facts, as far as I know them, is, that apparently in treating average- and low-grade ore of the district amalgamation can be eliminated; that if amalgamation is eliminated and solution introduced at the stamps, a considerable saving in operating cost, cyanide, and dissolved gold losses is possible.

"Unquestionably more extensive study has been given to the treatment of the Dome ore than to any other in the district. Hence one hesitates to make what may appear to be a criticism of an operating system probably justified by a careful balancing of co-ordinate factors by an eminent firm of metallurgists. However, no metallurgical discussion would be complete without touching upon this point, which is the salient difference between the two metallurgical systems of the district."

On the subject of concentration vs. non-concentration, it is Mr. Cunningham's opinion that concentration warrants careful consideration on the score of being able to give a portion of the ore the special treatment it demands instead of subjecting the entire ore to treatment necessary for only a part of it.

For agitation, the author considers the Dorr agitator well adapted to the treatment of the quick-settling and granular slime, particularly on account of being able to give selective agitation to a part of the ore requiring longer treatment. As to filters, pressure filters will be found more satisfactory than vacuum on account of the quick settling nature of the ore, causing difficulty in maintaining a pulp of uniform density and giving rise to uneven and channeled cakes. Continuous decantation is regarded as specially applicable to Porcupine ores, without the use of filters.

Zinc

Concentration at the Timber Butte Mill.—In a paper read before the Montana Society of Engineers, Butte, Mont., Mr. Theodore Simons described the concentration process used at the Timber Butte mill in treating the zinc ores from the Elm Orlu mine. The mill site on the northern slope of Timber Butte affords the following advantages: gravity system of ore flow; extensive area for tailings; good water supply and transportation facilities. The ore contains zinc and lead as sphalerite and galena; copper as bornite, chalcocite, tennite and tetrahedrite; gold and silver free and chemically combined with the base-metal sulphides. The gangue is quartz, barite, fluorite, rhodonite and rhodocrosite. Iron occurs as pyrite. Lead occurs in small quantity only, 0.75 per cent., and consequently a large expense for its recovery is not warranted. Moreover it is intimately associated with zinc and other sulphides so that a separation is difficult. The percentage of iron is 3.29, and of zinc 18.52. In order to make a satisfactory recovery of the lead and iron it is necessary to enrich those products at moderate cost and get something that will stand further refinement. This is accomplished by Wilfley roughing tables. These tables also recover from 25 per cent. to 30 per cent. of the total zinc in the ore at small cost. With the exception of this roughing operation, the only other gravity separation of mineral is performed on James tables that retreat the coarse part of the finished flotation product. Otherwise, all concentration is by flotation. The capacity of the mill is 450 tons of ore per 24 hours. The ratio of concentration for zinc is 3:1, and for lead-copper-iron, 125:1. Extraction averages about 96 per cent. of the zinc and 92.6 per cent. of the silver.

The striking feature in the gravity-concentration section of the mill is the operation of the Wilfley roughing tables, so-called. They are the first concentrating machines encountered in the mill, and take the undersize from impact screens without any previous classification. The tables not only handle an unusual quantity of material, amounting to more than 100 tons per table,

but they make at the very outset a finished coarse-zinc concentrate, containing from 49 to 51 per cent. zinc, and not more than 4 per cent. insoluble. They also send all the fines coming from the mine and those made in the preceding crushing operations to two Akins classifiers to be separated from the tailings, after which they go directly to the Minerals Separations flotation section, where they belong. Thus none of the intermediate machines is encumbered with this troublesome material, and the losses incident to frequent handling of slimes are reduced to a minimum. All this is accomplished by a clever modification and distribution of the riffles by giving the tables a rather steep inclination (8 deg. to 10 deg.) and by adding the proper amount of wash water.

To unlock the finest included grains of sulphides from the adhering gangue, prior to separation, it is necessary to crush the Elm Orlu ore to between 40 and 60-mesh, maximum. It was found that to attempt to extract zinc from material finer than 40-mesh by gravity concentration gave a low grade of concentrates, and would require a costly installation. This led to the adoption of flotation, according to the process of the Minerals Separation Co. The pulp is kept at a uniform density in the proportion of 3 of water to 1 of ore, and is heated to a temperature of 130 deg. F. by the introduction of live steam. From tests it appeared that with the Elm Orlu ore higher temperatures did not produce better results, while temperatures below 125 deg. reduced the efficiency of the plant.

Sulphuric acid is mixed with the pulp at the rate of 7 to 8 lb. to every ton of original ore going through the mill. Oil is added in the proportion of 0.5 of a pound per ton. Oil is introduced in the mixing compartment of the first cell where the pulp is violently churned by the action of the agitator, which at this plant makes 265 r.p.m. and causes the propeller to run at a peripheral speed of about 1500 lin. ft. per minute. The aerated mixture passes through an opening into the flotation compartment, where the froth containing the sulphides of lead, copper, zinc and iron, as well as some of the richer middlings, immediately rises to the surface while the clean gangue and the leaner middlings drop to the bottom.

The flotation compartment has the shape of a spitzkasten, the apex of which is provided with a valve, adjustable by a handwheel. Through this valve the material that has settled to the bottom of the first cell is drawn into the adjoining cell by the pumping action of its propeller. The process is here repeated, and the sulphides which did not float in the first cell are given a chance to do so in the second, and so on. By the time the pulp has reached the seventh cell of the rougher machines the clean sulphides and the richer middlings have all been floated. The remaining middlings in their passage from cell No. 7 to cell No. 11 are separated from the tailings by the successive flotation of the middlings, until in the bottom of the last cell only clean tailings remain, which are taken to a Dorr thickener for extraction of the hot water. This is pumped to a tank to be reused in the flotation machines. The middlings overflowing from the cells Nos. 7 to 11 are reground in the Hardinge mills and returned to the flotation section.

The float concentrates from the first six cells of the rougher machine is a product rich in zinc (about 47.8 per cent.), but due to the presence of middlings still contains about 14 per cent. insoluble. It is therefore sent to the first and fifth cells of a 200-ton Minerals Separation flotation unit containing eight cells. This is known as the "finisher machine," because it makes a finished sulphide concentrate. On passing the pulp through the successive cells of the finisher the sulphides are floated to the surface, while the clean middlings ultimately reach the bottoms of the fourth and eighth cells, whence they go to Hardinge mills, to be reground and returned to the flotation section.

The float concentrates from cells Nos. 1, 2, 3, 5, 6 and 7 of the finisher machine is a finished sulphide product containing, besides the sulphides of lead, copper and iron, 52 per cent. of zinc and 3.5 per cent. insoluble. The fines in this product overflow as fine zinc concentrates from an Esperanza and a Richards classifier through which the product is passed, the coarser portion of which is retreated on James tables. On these tables the lead and iron are separated from the zinc, and the insolubles in the zinc concentrate are reduced to 3.5 per cent.

The overflow from cells Nos. 4 and 8 of the finisher machine, being apt to contain a varying amount of middlings, is returned by air lift to the same machine. The agitating compartments of the flotation cells are lined with cast iron, and the propellers are made of brass. All agitators of a standard machine are driven from one main shaft by gears, which are protected from dust by steel housings. Gears are placed so that propellers in adjoining cells revolve in opposite directions, thus equalizing the strains on the machines and power transmission.

X-Ray Examination of Metals

Use of the Coolidge X-Ray Tube in Metallurgy.—In the General Electric *Review* for February, 1915, Dr. WHEELER P. DAVEY describes the use of the Coolidge tube in observing the defects of cast metal. Copper cast without the addition of boron gives a radiograph showing the pores in the metal, while a radiograph of boronize copper is without spots. The radiograph can be made by a two-minute exposure, the current through the tube being 2.8 milli-amperes and the potential difference across the tube corresponding to a 10-inch parallel spark gap between points. The advantage of the radiograph in experimental work is obvious, as it permits the determination of defects without machining the metal or destroying the casting. It is possible, also, to make stereoscopic radiographs, showing defects in their entirety and estimating their depth. A wide field for further work is opened by this use of the X-ray tube.

Instruments

The Measurement of Rapidly Changing Temperatures is the subject of a discussion by ALFRED PETERSEN (*Zeit.* d. Ver. Duetsch. Ing., April 18, 1914; in abstract in *Bulletin* de la Soc. d'Encouragement, Aug.-Sept.-Oct., 1914, p. 328). To follow instantaneously the changes of temperature, for instance, in the cylinder of an internal-combustion engine, an electrical instrument must be used, either a thermocouple (platinum, platinum-rhodium) or an electric resistance pyrometer (platinum-iridium, containing 35 per cent iridium). For measuring the current an Einthoven string galvanometer is used, for calibration of the thermometers an electric furnace. Some experiments were made under what conditions variations of 1800 deg. C. during one-tenth second could be measured. For this purpose the thermo-element or resistance wire were mounted on a revolving disc, so as to carry them at the proper intervals through a Bunsen flame. Only thermo-couples of 0.02 and 0.03 millimeter or resistor wires of 0.02 millimeter reached the temperature to be determined in this time, and only the resistance pyrometer completely recovered its original temperature at the end of one-tenth of a second.

Table I

Crushing and Grinding

Heat Developed in Crushing.—An investigation made to determine whether the heat evolved in crushing could possibly indicate the energy used, has been made by Mr. James Cook, and reported in *Bulletin* No. 124, Institution of Mining and Metallurgy. The results are given in the accompanying Table I. The conditions of the experiment were as follows: The weight of the stamps was calculated to be within a few pounds of the round figure used, but no allowance was made for loss of weight during the three-day period of the test. The number of drops per minute was determined frequently. The average height of drop is only approximate, as it could not be determined continuously. The E.H.P. of the battery motor was read continuously and the average taken. The actual horsepower is merely the product of the estimated weight of the stamp, and the number and height of drops. The orifice of the screen used was accurately known, and various meshes were used to see whether the heat evolved varied with the mesh. The weight of water used and ore crushed were found by two methods: (*a*) gaging the water feed and the proportion of solid in the pulp sample; and (*b*) running the entire pulp into a measured tank for a certain time, and ascertaining the amount of water and solid.

The specific heat of the ore was calculated from an analysis of the ore to be 0.251, which was confirmed by a rough test in our laboratory.

The product of the number of pounds of ore crushed per minute, the specific heat, and the rise in temperature in degrees Centigrade, together with the product of the number of pounds of water per minute, its specific heat, and the rise in degrees centigrade gives the total heat units evolved per minute. This multiplied by 1390 —the number of foot pounds in one H.U. centigrade— divided by 33,000 gives the total horsepower per minute represented by this rise in temperature.

For the purposes of my original experiments the pulp was graded through I.M.M. screens as shown in the three examples given.

Of the E. H. P. supplied to the motor, it will be seen that only 76 per cent. is apparently stored in the raised stamp. The ore crushed will be seen to have been raised an average of 4.8 deg. C. while the water used was raised an average of 0.438 C.

The difference is due to the smaller portion of ore feed being at a lower temperature than the water feed.

The average temperature of the ore feed was ascertained at intervals by burying the thermometer in the ore shoot supplying the automatic feeder. This temperature was found to be practically constant.

The average temperature of the water feed was found by frequent tests.

After numerous experiments it was found that the best method of ascertaining the pulp temperature was to take large samples from the entire pulp stream into which the thermometer could be inserted and examined undisturbed.

The temperature of the building was not sufficiently above that of the pulp or feed to affect the temperature during the time of reading. The same thermometer was used to take all temperatures. This, though somewhat inconvenient, avoided any instrumental error.

The thermometer, a very sensitive one, divided into tenths of degrees centigrade, could be estimated easily to further sub-divisions by means of a magnifying glass.

Of the actual power input to the motor, practically 61 per cent. is returned as heat in the pulp. Of the energy which reached and was stored in the lifted stamp, practically 80 per cent. is returned as heat in the pulp. The 20 per cent. unaccounted for may be allocated as follows:

(*a*) Loss in friction with the guides; (*b*) loss in sound and vibration; (*c*) loss in radiated heat; and (*d*) energy with which the pulp is delivered through the screens.

At some points the screen had a higher temperature than the pulp, showing the energetic bombardment to which it was subjected by particles which partly passed or which were returned. From the table it will be observed that a difference of 3 per cent. in the heat energy was found with the two different meshes. The author is inclined to regard this as experimental error. The ore experimented on was a gold-bearing conglomerate.

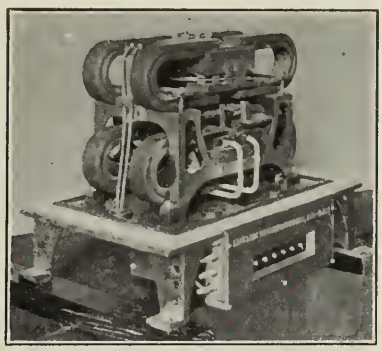
The safety-first publication of the Anaconda Copper Mining Co., known as *The Anode*, has made its appearance. It is designed to promote the safety of Anaconda men in various departments of work. We extend to *The Anode* our best wishes for a useful career.

A New Ampere-Hour Meter for Electrolytic Works and Refineries

In the electrolytic refining of metals, and in all electrolytic processes, the quantity of current used is one of the most important quantities to be measured. If measured in ampere-hours its quantity is directly convertible into pounds of copper or other metal deposited or into pounds of caustic soda and chlorine, obtained in the electrolysis of brine solutions, and affords a direct determination of the current efficiency according to Faraday's law.

It happens that in the development of the latest form of conveyor scales it became necessary to produce an ampere-hour meter of very much greater accuracy and permanence than any that had been constructed in the past and from which all delicate parts were eliminated. This resulted in the meter described below, which is also unique in the absence of any mechanical connection between the integrating element and the registering device.

The meter is of the well known mercury motor type, but the dimensions and weight of the parts have been increased many times over what has been customary in the past. The driving element, or motor chamber, is a shallow reservoir of mercury in which a copper disc revolves. Four heavy double permanent magnets with suitable pole pieces create the driving field. The torque produced is more than seven times as great as has been the usual practice. The shaft of the driving disc is extended upward and carries a large aluminium damping disc. The damping field is produced by four double magnets of the same size as the driving magnets, but with toothed pole pieces to increase the effect of the eddy currents. Above the damping disc on the same shaft is a small copper disc carrying one or more platinum points, which alternately pass just over the rim of two steel cups. Each of these cups is connected with a reservoir of mercury in such a way that a meniscus is produced which is gently swept by the platinum points. In this way a contact is effected which is available for operating the counter without drag upon the rotating shaft. The entire shaft with its driving and damping disc is floated in the mercury of the motor chamber so that there is a very slight upward pressure. The upper end of the shaft is a small polished pivot of hard steel which runs in a cupped diamond end jewel and the lower end of the shaft is simply held in place by a polished sapphire ring jewel. No oil of any kind is used on the jewels.



AMPERE-HOUR METER

The result is a meter with only one moving part the motion of which is entirely controlled by magnetic and electric forces. Not only is the driving force greatly increased, but mechanical friction is reduced to the vanishing point. This gives a speed to the meter shaft which is dependent only on the volume of current and which cannot change with the lapse of time on account of the absence of friction and mechanical wear, as well as the absence of lubrication, the condition of which would vary.

Passing now to the registering part, this is simply an electric counter of new design which constitutes a rather radical departure. There is a rocker shaft actuated by two electric counters. This rocker shaft is the only moving part except the six number wheels. There are no springs or ratchets. The rocker shaft carries a hermetically sealed glass tube containing a small quantity of mercury which oscillates with the motion of the counter, and makes and breaks a contact connected with binding posts on the outside of the meter. This auxiliary circuit is available for the connection of distant registers or recording instruments. When a recording counter is used the meter gives a graphic record of the operation of the plant for every hour of the day. In this way all shutdowns, even if of a few moments' duration, are plainly indicated, and the quantity of current delivered during any hour or any fifteen minutes of the day or night is plainly read.

The meter is equipped with suitable shunts making it available for any volume of current that is to be measured. It is manufactured by the Electric Weighing Company, 180 Thirteenth Avenue, New York City.

The Analoid Method for the Determination of Phosphorus in Steel, Iron and Slag

The standardization of analytical routine methods in iron and steel laboratories is making further progress, as is instanced by the success and further development of the "analoid method" of analysis. Invented by the English steel chemists, Messrs. C. H. & N. D. Ridsdale, and introduced in this country by the Scientific Materials Company of Pittsburgh, this method depends on the use of "analoids," that is, tablets containing just the exact quantities of the proper reagents, which have been carefully tested and apportioned to give the best result for a certain reaction in the method for which they have been specially prepared.

In our issue of December, 1914, we described the analoid method for the determination of manganese in steel, iron ore, and slag. The analoid method of determining phosphorus is perhaps of still greater value for the routine laboratory and will be described in the following article:

Preparation of Sample.—Metallic samples consisting of moderately fine drillings are suitable; however, with 0.6 to 0.8 carbon steels or higher the samples should be very fine to facilitate solution. Cast iron, should, if drilled, consist of very fine drillings, preferably pounded afterwards, or if shot samples, should be pounded to pass a 60-mesh sieve. Slags, etc., should have the same fineness.

Preparation of Solutions.—Reagent No. 1.—Nitric acid. Mix 21.5 parts nitric acid, 1.42 sp. gr., with 10 parts by volume of 3 per cent (at least) hydrogen peroxide.

Reagent No. 2.—Ammonium molybdate. Add 300 cc. of distilled water to 74 grams of molybdic acid (MoO_3) and mix well, add slowly 60 cc ammonium hydrate, 0.90 sp. gr. (or more, if not neutral to litmus), warm to not over 50° C. to aid in solution, filter and dilute to 1 liter with cold water.[1]

Reagent No. 3.—One-sixth normal sodium hydroxide (6.667 grams per liter). This solution can be prepared free from carbonate by making a saturated solution of NaOH (by alc.) in about 50 cc of distilled water. Enough NaOH must be used so that some remains undissolved together with any sodium carbonate. Allow to settle and decant clear solution into a bottle which

[1] The operator should be cautioned not to use an acid solution of molybdate, as it alters the proportioning of the reagents, volumes of liquid, temperature of precipitation, and gives erroneous results, unless proper allowance is made.

must be kept stoppered. Use 6 to 7 cc of this solution per liter of distilled water. Standardize against steel of known phosphorus content.

Reagent No. 4.—Nitric acid. Make a nitric acid solution exactly equivalent to the above sodium hydroxide solution which will be approximately correct by diluting 20 cc nitric acid, 1.42 sp. gr., to 2 liters.[2]

Procedure for Steels up to 0.3% Phosphorus.—Place the 2-gram sample in a 300-cc Erlenmeyer flask which has an approximate graduation mark at 55 cc, and add 55 cc of reagent No. 1 (nitric acid). After vigorous action has subsided, cover with small watch glass and heat at just below the boiling point until solution is complete and the brown fumes practically expelled.

Add one No. 4 analoid and heat gently for two minutes to destroy all soluble carbonaceous matter and insure complete oxidation.

Then add one No. 5 analoid, bring quickly to boil till clear, then hold at just below boiling for at least two minutes. Rinse cover of flask and dilute to 55 cc (if volume is less) with boiling water. Now precipitate the phosphorus at a temperature of 72-78° C. by adding to the boiling solution 20-25 cc of cold (10°-19° C.) neutral ammonium molybdate solution No. 2 giving a total volume of 75 to 80 cc. Shake well (vertical motion) for full two minutes and allow to settle (stoppered) for about two minutes at about 40° C. If phosphorus is low shake 5 minutes and allow to settle 10-15 minutes.[3]

A yellow precipitate, both chemically and physically perfectly uniform, granular to facilitate filtering and washing, is produced. These qualities render it especially suited to centrifugal machine treatment to produce reliable results. The precipitates so obtained may be filtered and finished by any of the customary methods, but the following method is recommended.

Filter through good quality analytical filter paper using suction, rinsing the flask with 2 per cent nitric acid, and washing till free from acid, with a solution made by dissolving one analoid No. 14 in 30 to 40 cc of hot water, cool and dilute with distilled water to one litre.[4]

The paper is removed from the funnel placed open against the inside of a 250 cc beaker, and the necessary amount of 1/6 normal sodium hydroxide solution (20-25 cc) allowed to wash the precipitate into the beaker, using an accurately graduated pipette or burette. The liquid is stirred with a glass rod until dissolved, the filter paper broken up in the solution, 100-150 cc of cold distilled water added, also 1-2 drops of phenolphtalein solution (1-100 alcohol) and the excess of sodium hydroxide titrated back with the equivalent nitric acid solution.

The difference from total NaOH used gives the number of cc. reacting with the ammonium phosphomolybdate. This multiplied by the phosphorus factor gives percentage of phosphorus (or weight if so calculated).

Procedure for Cast Iron and Pig Iron.—Sample 2.857 grams (for percentage up to 0.3 phosphorus) placed in a 250 cc beaker and dissolved in 75 cc of nitric acid solution No. 1, covered and heated gently until brown fumes are expelled. Transfer to a 100 cc flask, dilute to exactly 100 cc with cold water, shake and filter through dry filter into a dry beaker. Exactly 75 cc are transferred to a 300 cc erlenmeyer flask graduated at 75 cc. (This gives a sample equivalent to 2 grams of iron). Cover flask and heat just to the boiling point and add one analoid No. 4, simmer at least two minutes and add one analoid No. 5, heat quickly to boil until clear, then simmer at least 2 minutes. Dilute to 75 cc with boiling water and precipitate at a temperature of 68-72° C. by adding to the boiling solutions 25 cc of cold (10°-19°) neutral solution of ammonium molybdate No. 2 diluted to 40 cc with cold water, shake 5 minutes, then allow to stand as directed in procedure for steels.

The method with slight modification is adapted for analysis of high-phosphorus irons (up to 3 per cent), also to high-phosphorus slags and fertilizers.

We have described in detail the analoid method for phosphorus determination, in order to bring out in which regards it means a considerable simplification of usual methods. This matter is gone into with greater detail in a pamphlet just issued by the Scientific Materials Company of Pittsburgh, Pa.

[2] Although solutions No. 3 and No. 4 are for use in the "acid-alkali" method, any of the usual methods may be used after the precipitation of the yellow precipitate.

[3] If the solution is allowed to stand in a warm place much longer than the prescribed time, arseno and silico molybdates may be more or less precipitated and give a high result; but if at ordinary temperature, 18-23° C., this is usually avoided.

[4] This removes the acidity without dissolving the yellow precipitate whereas water if used would dissolve it.

Sentinel "Pyrometers" and Paste and Their Uses

A new method for measuring temperatures, similar in principle to Seger cones, has been developed by the Carl Nehls Alloy Company, of Detroit, Mich. Different kinds of metallic salts have been made up of such chemical compositions as to have definite different melting points throughout the temperature range between 425

FIG. 1—SENTINEL PYROMETERS AND PASTE AS MADE AND USED

and 2425 deg. Fahr. (218 to 1329 deg. Cent.). They may be used, like Seger cones, for measuring temperatures, and are also very useful for checking pyrometers. For the latter purpose a cylinder is placed at the end of the thermocouple and when it melts the pyrometer should read the same as the temperature marked on the "Sentinel."

One way of using these metallic salts compositions is to cast them into solid cylinders, 7/16 in. in diameter and 3/14 in. long, as shown by those standing on one end in Fig. 1. Each one is wrapped in a paper on which is printed its correct melting temperature in degrees Centigrade. These are shown by the samples lying down. For all temperatures below 932 deg. Fahr. these "sentinel pyrometers" can be used in an air-tight glass tube such as is shown in the center. The salts can then be used over and over again. By using the small porcelain saucer shown, the salts do not run to waste and litter up the place where they are used. This also enables them to be used several times, as the salt will melt each time the temperature raises above the one marked on the cylinder and it will become solid again the moment the temperature falls below this degree.

These salts are also made up in the form of a paste.

Enough to make several hundred determinations is packed in the tins shown. Pastes with various melting temperatures can be daubed along a steel bar, as shown in the front of Fig. 1, and inserted into ovens, furnaces, retorts, flues, gas mains, steam pipes, etc., to find the temperature at which they are operating. The salts that melt down and those that remain solid will indicate the temperature which would be between the two. By using a long bar one can determine whether the temperature is uniform in the front and back, top and bottom, or corners of a furnace, oven, kiln, etc.

This is an easy method for obtaining the exact temperature of tools heated in a forge fire. A paste is

FIG. 2—"SENTINEL PYROMETER" USED IN TUBE IN POT FURNACE

selected that represents the correct hardening temperature for the tool. This "sentinel paste" is daubed on the tool and when it is heated to this temperature the salt will melt and the tool can be taken out of the fire and quenched. It will make it easier if the tool is surrounded by a piece of sheet steel or is inserted in gas pipe as that keeps the paste from coming in contact with the fuel.

Another handy way of using the "sentinel" cylinders is to plug one end of a tube or pipe and drop a sentinel cylinder into the tube. A small rod can then be lowered into the tube and made to rest on the salt. When the salt melts down the rod will lower and thus indicate that the melting temperature of the salt has been reached. This is very useful for finding the temperature of molten metal, salt bath furnaces, etc. Fig. 2 illustrates this method.

A Special Paper for Recording Instruments, Drawings and Similar Purposes

A chemically surfaced paper of high merit has recently been put on the market by the Non-Carbon Paper Company, 14 Federal Street, Boston, Mass., which should be of considerable interest to manufacturers and users of recording and registering instruments. Several years of experimenting and a large expenditure have been necessary to produce a product of this kind.

To produce a paper which would be satisfactory as a chart for the various kinds of instruments, some requiring a sensitive surface and some a hard one, was the problem to be solved. Further, a surface had to be created upon which printing could be done satisfactorily for the making of charts, graphs, tapes and other devices. Then the sensitiveness had to be satisfactory within the wide range from the recording instruments requiring a firm surface to the more sensitive finish required by instruments of a delicate nature. These problems have all been worked out and a high-grade paper manufactured to fit any and all of these needs.

Another valuable feature of this paper is its utility in the engineering department for the production of sketches and drawings. A still wider field is opened up by the fact that this paper is especially valuable in the second-sheet field, where records of correspondence may be made through its use without the aid of carbon paper. This paper is adaptable to auto trucks and vehicle recorders, speedometers, electric and water meters, steam gauges and water-pressure instruments, recording thermometers, pyrometers, hightenographs, magnetographs, time locks and time registers, movement indicators, fatigue testing instruments, pulsation recording and respiration registering devices, pneumatic orbits or movements of scientific machines. Copies of records can be obtained by inserting sheets corresponding with the form print.

Bronze Castings as a Substitute for Steel Parts

Machine parts of steel are inexpensive as far as the cost of the material is concerned, but if the cost of machining, grinding, hardening, finishing, etc., is considered, they may become so expensive that their equal weight in bronze or silver, or even gold, will be worth less. Often a preferable machine construction has to be abandoned for the reason that the making of one or more of the necessary parts cost too much if same have to be machined, especially in quantity work.

Where strength, toughness, resilience, wearing quality and durability could be neglected, the products of the white-metal die-casting industry overcame the obstacle caused by the high machining cost, as its products leave the moulds smooth, true and accurate, and therefore need little finishing work. However, the good qualities of steel, either soft or hard, can be reached and even greatly excelled by brass (copper with zinc), bronze (copper with tin) and other modern copper-base metal compositions, but against their use stands their high material cost unless the same can be balanced by the saving of finishing labor, as is often the case.

If, however, it becomes possible to produce also copper-base metal composition die castings smooth and accurate, then the saving of finishing expenses in many instances would excel the higher cost of the material, and at the same time there would be an opportunity of substituting a superior material for the steel.

The McGill Metal Company of Valparaiso, Indiana, has entered this new field of industry, that is, of casting copper-base metal compositions in permanent steel moulds or dies. After systematic experimental work and after furnishing bronze-die castings for two years to a limited number of customers for thorough tests, this company saw such an encouraging success that it is now erecting a new permanent foundry and die shop with a modern equipment for making bronze castings in permanent steel moulds.

Among the many difficulties which the experimental plant had to overcome were: To work out bronze compositions of perfect equilibrium at all temperatures,

and of sufficient strength, even at a high temperature to withstand all strains caused by its own shrinkage around the steel cores in the dies. Even the best brasses and bronzes used commercially heretofore fell short in these requirements, likewise no make of steel found on the market did meet the requirement of withstanding the attack of molten metals at temperatures of from 2200 to 2400 deg. F., as is needed with the mould material. Therefore, special steel alloys had to be developed to suit the purpose.

One of the fields in which the McGill metal castings worked remarkably successful was the quantity production, at a reasonable price, of strong, tough, hard and durable bevel-gears with correct teeth. As is well known, the cost of cutting correct bevel gear teeth is prohibitive in regular quantity manufactured, however, if the cutting of correct teeth need to be done for once only in a die, and if in this die hard and tough bronze can be cast successfully the production of strong and correct bevel-gears can be accomplished without needing any mechanical work at all on the teeth. And if the material is superior to correctly case-hardened or tempered steel in every respect, then also the manufacturer avoids the uncertainty and risks of the heat treatment of steel. These aims are accomplished by the McGill metal casting process.

The McGill metal castings are finely granular or fibrous and homogeneous, have a great cohesion and flowing power even with their hard varieties; they can be forged red hot or cold, and can be machined with ease. Vibrations, shocks, strains as well as heat if within reasonable limits will not influence their fine and uniform grain, nor their strength, hardness, toughness and springiness as continuous exposures for two years have proven. Those qualities can be regulated by varying the compositions. Not being attained by secondary treatments these qualities being innate will last and not change in time or by use.

The castings take a high polish on account of the fine close grain, and will practically show almost no wear even when run without lubricator, under great load, and with great speed. Therefore, they are ideal where subject to rolling, sliding or pounding, as is the case with gears, cams, clutches, couplings, sliding (reciprocating or rotating) valves, poppet valves, bearings and bushings.

The color of the metal is a golden yellow. It contains about 90 per cent copper and withstands well the action of acids, alkalies and salts. The users of the material will not be troubled with rusting and corroding, nor with pitting. Against the latter the hardness and closeness of its grain is an additional protection.

Physical tests with the material gave the following results: Tensile strength, 75,000 to 85,000 lb. per square inch, with an elastic limit of 30,000 to 40,000 lb., and elongation of 18 to 23 per cent on a 2-in. test length, and a reduction of area of 17 to 24 per cent.

Portable Welding Outfit for Metallurgical Works

The rapid progress made by autogenous or fusion welding throughout the metal industry is an indication of the numerous advantages possessed by the process. The object of this method of welding is to bring the metal, at the point of treatment, to a liquid state so that the parts to be united will fuse and flow together in a practically homogeneous piece. The heat employed for the purpose may be generated either by electricity or by means of thermit or by burning a combustible gas with oxygen.

Acetylene gas is highly suitable for the purpose, the temperature of the oxy-acetylene flame being about 6300 deg. Fahr. The decomposition of acetylene (C_2H_2) when burned with oxygen presents some features valuable in welding. The high temperature of the oxy-acetylene flame, caused by the combustion of carbon, is above the temperature of dissociation of steam, so that water is not formed as a product in the flame. The hydrogen from the acetylene does not enter into combination with oxygen until after it has left the high-temperature zone of the welding flame. This produces a zone of hydrogen, more or less free, surrounding the welding flame, giving a reducing atmosphere and preventing oxidation of the metal.

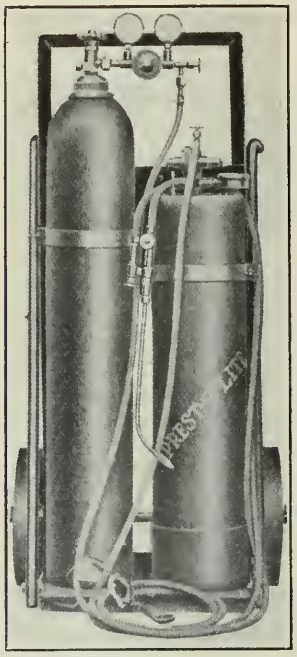


FIG. 1—PORTABLE WELDING OUTFIT

The application of oxy-acetylene welding is a comparatively simple matter in ordinary work, and men are readily trained to use it efficiently. The process, therefore, is one that can be profitably applied in repairing broken machinery in concentrating and cyanide mills, smelters and metallurgical works generally. At isolated plants it is especially valuable in reducing losses incident to broken machines, and avoiding delays due to getting new parts or sending broken ones out for repair.

The process has been made particularly available for this kind of work through the portable Prest-O-Welder outfit, which has been placed on the market by the Prest-O-Lite Company, Inc., of Indianapolis, Ind. As shown in Fig. 1, it consists of two cylinders, with pressure gages, hose, blow-pipe and tips, mounted on a truck. One of the tanks contains compressed oxygen and the other acetylene prepared according to the Prest-O-Lite process. The oxygen cylinder can be recharged at various places in the country, and the Prest-O-Lite cylinder is exchangeable through the company's numerous service stations which are widely distributed.

The entire outfit weighs less than 300 lb., and being portable and compact, it affords the greatest convenience and efficiency. In this respect it is superior to stationary acetylene generating apparatus, to which repair work must be taken, often at added expense or inconvenience. The purity of Prest-O-Lite gas is an added advantage over that generated from carbide and water, for the impurities in the latter affect the weld and can be removed only through the use of expensive apparatus. Further, Prest-O-Lite will not freeze in cold weather and is always ready for use. The entire apparatus is simple, durable, convenient, safe and under perfect control. Considering these features, it should find a broad field of usefulness in mills and smelters.

The Iron and Steel Market

Steel mills at the end of February were operating at between 55 and 60 per cent of capacity. Operations in January averaged fully 45 per cent of capacity and the average for the first two months of the year is fully 50 per cent, against about 35 per cent in November and December.

The recovery in demand is real, but it is halting and

hesitating. The mills have maintained their increased rate of operation only by making up their rolling schedules at short intervals, practically from day to day, and any decrease in the current demand would at once be followed by decreased operations.

There has been little if any increase in the demand for steel for important permanent investment. The railroads have taken a very small part in the buying, and there is very little in the way of large structural enterprises. It would appear that what has occurred is simply that towards the close of the old year jobbers and manufacturing consumers drew upon stocks, causing mill production and shipments to fall below the actual rate of ultimate consumption, and that since the first of the year this factor has disappeared, while there has been a slight increase in consumption.

The hopes of the steel trade now rest upon an increase in consumption due to the near approach of spring, permitting an expansion in outdoor work and due also to the better financial and economic conditions which should lead to the investment of capital in extensions and new enterprises.

Export trade holds out no great hopes, as there were declines in November and December from the record of October. Exports of iron and steel, including scrap, pig iron, rolled iron and steel, cast and wrought pipe, wire, nails, etc., have been as follows, in gross tons:

January	118,770	July	114,790
February	121,206	August	86,599
March	159,998	September	96,476
April	161,952	October	147,293
May	139,107	November	140,731
June	144,003	December	117,655

Year—1,548,680

For about a year and a half the steel industry has been operating at all times at considerably less than its capacity and while statements are made in the trade with more or less confidence that this or that plant, or the industry as a whole, is operating at a certain percentage of capacity, it is doubtful whether the real capacity is definitely known. It is possible that under the most favorable circumstances an output could be attained much beyond the rated capacity, and it is equally possible that upon short notice the industry could not reach a rate of operating even at nominal capacity, there being in the chain so many links of uncertain strength. It might be therefore that with a further and only moderate increase in demand the mills would begin falling behind in deliveries of some products. Such an event would undoubtedly arouse overnight a demand for hundreds of thousands of tons of steel, as jobbers and manufacturing consumers are operating with extremely light stocks, being able as a rule to secure shipment from mill a few days after the filing of specifications, and any question raised as to the promptness of shipment would at once induce these buyers to attempt to add to their stocks. Despite the very conservative views entertained on all hands as to the future of the market in the next few months there is a distinct possibility of a period of decided activity marketwise with consequent sharply rising prices.

Pig Iron

The pig-iron markets throughout the country have been showing remarkable steadiness in prices and a very decided lack of activity at the same time. The buying movement of late in the old year seems to have covered consumers comfortably, as to their present rate of operation, as there are practically no complaints of consumers not taking deliveries as contracted for, yet the total production continues light, as light as for several years. There has been a sharp increase in pig-iron production by the steel interests, but none by the merchant furnaces. As many of the existing contracts are for the quarter only, an increase in buying is expected in March. Quotations show scarcely any change from those of one month or two months ago, and are as follows: No. 2 foundry, Birmingham, $9.50; delivered Philadelphia, $14.50; f.o.b. furnace, Buffalo, $13; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13; at valley furnaces (95 cents higher delivered Pittsburgh) Bessemer, $13.60; basic, $12.50; No. 2 foundry, $12.75 to $13.25; malleable, $12.75; gray forge, $12.50 to $12.75. Ferromanganese on contracts is nominal at $68, Baltimore, there being question about delivery on account of the embargo. Small prompt lots have been commanding $85 to $100, a decided advance in the month.

Steel

It develops that one or two of the Youngstown mills did not secure as much billet and sheet bar business as desired, and they have not participated in the advances made by Pittsburgh mills, the result being that quotations at Youngstown are substantially as low as a couple of months ago, while the Pittsburgh mills are forced to be content with their contract tonnage and are not naming competitive prices. We quote billets at $18.25 to $18.50 and sheet bars at $18.50 to $19, f.o.b. maker's mill, Youngstown, and $1 higher delivered Pittsburgh. Rods are $25 to $26, Pittsburgh.

Finished Steel

In December the regular market for bars, plates and shapes was 1.05c. for specifications to be filled in December for early shipment, 1.10c. for first quarter contracts and 1.15c. for second quarter. At the end of December the 1.05c. price was withdrawn. Early in February former prices for forward deliveries were withdrawn, mills then quoting 1.10c. for February specification, 1.15c. for March and 1.20c. for second quarter, in substance leaving it to the calendar to effect an advance, and the question is whether the beginning of March will witness a disappearance of the 1.10c. price. At the same time the National Tube Company began quoting steel pipe at a one-point advance for specifications to be filed in April, and a two-point advance for May and June. This was followed on February 11 by the issuance of a new list with a straight advance of one point on black steel pipe 6-inch and under, and an advance of three points on galvanized steel pipe ¾ to 6-inch, this extra advance on galvanized pipe being due to the record high price and extreme scarcity of spelter. Effective February 12 wire products were advanced $1 a ton. The continued advances in spelter forced higher and higher prices for galvanized sheets and in the last week in February all the mills that were quoting at all advanced to 3.40c. for 28 gage, even then accepting orders only for immediate specification and prompt shipment. Nominally the advance due to the advance of spelter to nine cents or higher is $13 a net ton, but practically it is $16, as while the openly quoted market had not gone below 2.75c. there were some contracts made in December at 2.60c.

Current quotations are as follows for ordinary deliveries, quotations being f.o.b. Pittsburgh unless otherwise noted.

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.10 to 1.15c.

Shapes, 1.10 to 1.15c.

Steel bars and bands, 1.10 to 1.15c.; base, hoops, 1.25 to 1.30c.

Refined iron bars, 1.15c., Pittsburgh; common iron bars, 1.12½c., Philadlphia; 1.05c., Chicago.

Sheets, blue annealed, 10 gage, 1.30c.; black, 28 gage, 1.80 to 1.90c.; galvanized, 28 gage, 3.40c.; painted cor-

rugated, 28 gage, 2.00c.; galvanized corrugated, 28 gage, 3.45c.

Tin plate, nominal price $3.20 for 100-pound cokes; large lots at $3.10 or possibly less.

Steel pipe, ¾ to 3-in., 80 per cent off list.

Steel boiler tubes, 3 1/3 to 4½-in., 74 per cent off list.

Standard railroad spikes, 1.35c., Pittsburgh; 1.45c., Chicago.

Cold rolled shafting, 68 per cent off list.

Structural rivets, 1.35c.; boiler rivets, 1.45c.

Chain, ⅜-in. proof coil, 3.00c.

Montana Section of American Institute of Mining Engineers

The annual meeting of the Montana Section of the American Institute of Mining Engineers was held in Butte on the evening of Feb. 5. More than fifty members and guests enjoyed a dinner at the Silver Bow Club preceding the business and technical session. The following officers were elected for the ensuing year:

Chairman, F. M. Smith, manager East Helena plant of the American Smelting & Refining Company.

Vice-chairman, J. L. Bruce, manager of the Butte & Superior Copper Company.

Secretary-treasurer, D. C. Bard, professor of geology, Montana State School of Mines.

Executive committee, Frederick Laist, chief metallurgist Anaconda Copper Mining Company, and W. C. Siderfin, manager of the W. A. Clark interests in Montana.

The secretary's report shows an active membership in the state of 160. Arrangements were considered for having the Montana Section represented at the San Francisco meeting of the Institute next September.

Two technical papers were presented and discussed. One on the concentractor of the Timber Butte Milling Company, by Theodore Simons, (see Synopsis in this issue), the other on "The Boulder Batholith of Montana," by Paul Billingsley. The Montana Section of the Institute meets twice a year. It is growing in membership, and its usefulness is being increased as interest in the organization grows among mining men.

Personal

Dr. Lucien I. Blake, of Boston, is expected in Denver March 1. While there he will deliver a series of ten lectures on Cosmic Physics before the Teknik Club, and an additional course on Molecular Physics at the Colorado School of Mines.

The Colorado Iron Works Company has opened a down-town office in Denver for the accommodation of its friends and customers who may find it inconvenient to visit the main office at the works. The new office in the Ideal Building, Seventeenth and Champa Streets, is in charge of Mr. Hugh B. Lowden, secretary of the company. Mr. Randall P. Akins, sales manager, will also make this office his headquarters when in the city.

Mr. C. A. Filteau has sailed from New York, via Panama, for Carabaya, Puno, Peru, where he will manage the affairs of the Inca Mining & Development Co.

Mr. Robert A. Marr is metallurgist for the Platinum Mining & Milling Co., at Holmes, Wyo.

Mr. Arthur G. McKee announces that **Mr. Robert E. Baker** and **Mr. Donald D. Herr,** his business associates during a number of years past, have joined him in the incorporation of the engineering and contracting firm of Arthur G. McKee & Co.

Mr. Philip S. Morse, who has been manager of the mines, mills and smelting works of the Sulphide Corporation in New South Wales, has resigned his position and returned to the United States.

Messrs. Jacques Negru, Paul S. Nice and **Thomas Charlton,** all of Denver, Colo., have associated themselves as the Chemical and Engineering Institute. A general consulting business in chemical engineering will be conducted with offices in the Central Savings Bank Building.

Mr. Edgar L. Newhouse has been chosen first vice-president of the American Smelting & Refining Co., succeeding the late Barton Sewell. Messrs. Edward Brush and S. W. Eccles also have been advanced in the line of vice-presidents.

Prof. **Robert H. Richards** has been awarded the gold medal of the Mining and Metallurgical Society of America, in recognition of his services in the advancement of the art of ore dressing. The formal presentation will not take place until March.

Mr. W. G. Swart, mining and metallurgical engineer of Denver, Colo., with offices at the Foster Building, has joined the Hardinge Conical Mill Company in the capacity of consulting engineer in the West.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Electroplating Alloys

98,110, Dec. 21, 1869, Samuel Rust, Jr., of Cincinnati, Ohio.

Relates to electrodepositing brass and other alloys upon iron, zinc and other metals, and an apparatus therefore, which consists of a large tank having a steam-coil on the bottom. The solution is made as follows: First solution, 1¼ lb. of cyanide of potassium, 1⅜ lb. of carbonate of ammonia, 1 gal. of distilled water; second solution, ½ ounce of bisulphide of carbon, 4 ounces of cyanide of potassium, 1 pint of distilled water, shake until dissolved. To 1 gal. of the first solution add ½ ounce of the second solution, mix and allow to stand for twenty-four hours, or longer. Before using decant as much as possible of the clear solution and filter the remainder from any sediment. Fill the tank and a porous cup with the clear solution, in the porous cup place a brass or copper cathode, and a sheet of brass for an anode in the outer tank; pass a current until the required amount of brass has been dissolved, then remove the porous cup and cathode. The solution is now ready for use. The temperature should be about 180 deg. Fahr.

103,947, June 7, 1870, William Henry Walenn, of London, England.

Relates to electrodepositing brass and describes several electrolytes, one of which is as follows: One part by weight of crystallized sulphate of zinc, two parts by weight of crystallized sulphate of copper, are dissolved in the least possible water. Sufficient strong ammonia water is added to precipitate and then fully redissolve the oxides. The purple tint of this solution is completely removed by a standard solution of cyanide of potassium, left to stand for a day or two, and may then be worked with from one to three battery cells, using heat if a brass anode be employed. The patent should be consulted for further details.

155,700, Oct. 6, 1874, Edmond Boy, of New York, N. Y.

Relates to preparing an electrolyte for depositing an alloy to be used for ornamenting articles of copper, iron, etc. The solution is prepared as follows: To about 200 parts by weight of hot water add twenty parts of powdered arsenic, (probably uses one of the oxides of arsenic); after solution, add twenty parts of cyanide of

potassium, and allow the liquid to remain until it is clear. Grind together one part of sulphate of copper, one part of sulphate of zinc and four parts of carbonate of soda, dissolve in water and mix with the above solution, stir thoroughly and allow to stand. A small quantity of cyanide of potassium may be required to perfect the solution. For use the solution is kept at a boiling heat, the article to be plated suspended therein as cathode and platinum or other metal used as anode. A strong current is required. The deposit obtained is of a lustrous bronze color and highly ornamental.

223,210, Dec. 30, 1879, William Frishmuth and Herman B. Van Tronk, of Philadelphia, Pa.

Relates to electrodepositing an alloy of nickel and aluminium, from an electrolyte containing 6 ounces of nickel chloride, 2 ounces of a mixture made of two parts of chloride of aluminium to one part of chloride of sodium, the proportion of nickel salt and mixed aluminium-sodium salts being dissolved in 1 gal. of water. A strong current is passed through the solution from a nickel anode to a carbon cathode, until the solution is in proper condition for plating, when the carbon is removed. The solution is now ready for use. In place of nickel chloride there may be used nickel sulphate or nickel nitrate.

228,900, June 15, 1880, James S. Howard, of Springfield, Mass., assignor to James M. Abbott, of Waterbury, Conn.

Relates to an improvement in solutions for electroplating with an alloy of which aluminium is the base. One pound of a mixture of one part cryolite, one part chloride of magnesium and one part chloride of manganese, combined in the form of a powder is added to 1 gal. of water and boiled until thoroughly dissolved. The granulated alloy anode is placed either in an open network or may be placed on the bottom of the lead-lined tank, in which latter case the current is connected to the lead lining.

231,064, Aug. 10, 1880, George Linsenmayer, of Philadelphia, Pa.

Relates to electrodepositing an alloy of aluminium and gold from a solution prepared as follows: First solution: To 10 liters of distilled water add 7 ounces of phosphate of soda, 1½ ounce of sal-ammoniac and 1 ounce of magnesia. Second solution: To 5 liters of distilled water, add 2 ounces of bicarbonate of soda, ½ ounce of muriate of soda, ½ ounce of flowers of sulphur and 1 dwt. of acetic acid. Third solution: To 8 liters of distilled water, add 10 ounces of cyanide of potassium and 15 dwt. of spirits of wine. When all the substances are dissolved pour the three solutions together and boil for half an hour, cool and add 2 ounces of burnt alum dissolved in 1 liter of water, 1 ounce of aluminium and 1 ounce of gold, the latter previously dissolved in nitro-muriatic acid and 4 ounces of cyanide of potassium with 1 ounce of aqua-ammonia. Boil again for half an hour, then filter while hot. The solution is now ready for use; it should be used at a temperature of 180 deg. Fahr. to 200 deg. Fahr.

248,554, Oct. 18, 1881, Milton H. Campbell, of New York, N. Y., assignor to himself and Norvin Greene, of same place.

Relates to electroplating silver or silver-plated ware for the purpose of protecting their surfaces from corrosion or tarnishing. The articles are plated with a homogeneous alloy consisting of from twenty-five to thirty-six parts of platinum and seventy-five to sixty-four parts of silver. With less than ten parts of platinum the alloy is not capable of resisting the stronger corrosive agents, such as nitric acid and the sulphides. In making the plating solution, the alloy is converted into a compound chloride of platinum and silver, by dissolving in nitric or nitro-muriatic acid, heated to boiling. This solution is diluted with about four times its volume of water and then a hot saturated solution of chloride of ammonia is added to precipitate the chlorides. About 1 ounce of the compound chloride is dissolved in 1 gal. of water, with a sufficient quantity of cyanide of potassium added thereto to afford a clear solution, which is used as the electrolyte. In electroplating, an anode of the alloy of platinum and silver is used. (See also his later patent No. 253,159.)

253,159, Jan. 31, 1882, Milton H. Campbell, of New York, N. Y., assignor of one-half to Norvin Greene, of same place.

Relates to electroplating silver or silver-plated ware for the purpose of protecting their surfaces from tarnishing while in the wholesale and retail stock and contains a reference to his earlier patent, No. 248,554. The deposit of alloy of platinum and silver described therein should weigh about 6 grains per square foot of electroplated surface. Such a thin deposit will not withstand wear; a heavy deposit is recommended for permanent protection. The current used to effect the deposit should not be too strong or silver will deposit almost exclusively. A current that will deposit 6 grains of alloy per square foot in five minutes is considered about right, although a still feebler current is preferred.

Book Reviews

The Fixation of Atmospheric Nitrogen. By **Joseph Knox.** 5 by 7½ in., 112 pages; price, $0.75. New York: D. Van Nostrand Company.

The author is lecturer on inorganic chemistry in the University of Aberdeen. The theoretical principles are clearly explained, while the technical side is briefly sketched, being principally condensed from T. E. Norton's "Utilization of Atmospheric Nitrogen"—with acknowledgment. Those unacquainted with the subject will find it a good book to begin with.

Cyanamid. Its Manufacture, Chemistry and Uses. By **Edward J. Pranke,** B.Sc. Octavo (14 x 22 cm.), 112 pages; price $1.25. Chemical Publishing Company, Easton, Pa. Williams & Norgate, London.

The topics treated are: discovery and manufacture, properties, analysis, storage, fire and water hazard, decomposition in the soil, toxicity, fertilizing properties. The book is clearly and carefully written, and will be useful to anyone studying the properties and uses of cyanamid; its manufacture is treated altogether too briefly, apparently intentionally so.

Modern Technical Drawing. By **George Ellis.** Duodecimo (13 x 20 cm.), viii + 200 pages; price $2 net. London: B. T. Batsford. New York: D. Van Nostrand Co.

This strikes us as a practical and well-written book, well adapted to explain and illustrate the making of working drawings. The directions for lettering are plain and sensible, without any of the fancy half-illegible letters which so often disfigure drawings. A few directions as to making blue-prints would be a desirable addition. The chief chapters are upon othographic projection, isometric projection, oblique projection, perspective, free hand, practical geometry, lettering, and workshop drawings.

Die Theorie der Strahlung und der Quanten. Transactions of the Solvay Symposium, Oct. 30 to Nov. 3, 1911; with an appendix on the Development of the Quanten theory to August, 1913. Edited in German by A. Eucken. (Abhandlung Nr. 7 der Deutschen Bunsen-Gesellschaft für angewandte physikalische Chemie.) 16 x 24 cm, 405 pages, 24 illustrations; price 15.60 marks. Halle a. S: Wilhelm Knapp.

This is a collection of papers read at the Solvay

Congress by H. A. Lorentz, J. H. Jeans, E. Warburg, H. Rubens, M. Planck, M. Knudsen, Jean Perrin, W. Nernst, Kamerlingh Onnes, A. Sommerfeld, P. Langevin and A. Einstein, with appendix by A. Eucken. Among those taking part in the discussions may be mentioned Poincaré, Madame Curiè, Lord Rayleigh, Wien, Rutherford, Hasenöhrl and Lindemann, besides the authors of papers. There is some wonderful information and speculation in the volume, which make it highly instructive and stimulating to the student of advanced physics and chemistry. It is perhaps the best source of precise information about the Quanten hypothesis, which here appears as about half established and half in conflict with orthodox thermodynamics.

A Textbook of Chemistry. By **William A. Noyes.** Duodecimo (12 x 20 cm.), xv + 602 pages, 110 illustrations; price $2.25. New York: Henry Holt & Company.

Professor Noyes and his numerous assistants have worked three years on this book, and as it stands it embodies the experience of a whole chemical laboratory in the presentation of chemical facts and theory. In one way the book is commonplace, in that it presents the facts clearly but without enthusiasm, its tendency being rather to over-burden and discourage the student by too numerous and too detailed facts, without much appeal to his imagination. On the other hand, as a saving grace, there are frequent appeals to the student not to learn mechanically, but to analyze statements into their constituent parts, and reason out complex results from simple fundamentals.

Teachers who can incite enthusiasm for the subject by taking the students in hand and teaching the facts and theories in this analytical manner, will be able to use this text-book as a useful vade mecum in their class work.

Incidentally, we would register a warning against the tendency of text-books of chemistry to degenerate into small chemical encyclopedias. Dozens of good and useful chemical text-books have in successive editions suffered from elephantosis, with their usefulness as text-books varying in inverse proportion to their size. Even if the student learns from such monstrosities mere chemical facts (which is not true beyond peradventure), yet he probably learns from them less chemistry.

Filters and Filter Presses for the Separation of Liquids and Solids. From the German of **F. A. Bühler,** with additional matter relating to The Theory of Filtration and Filtration in Sugar Factories and Refineries, by **John Joseph Eastick.** 184 pages, 327 illus. Price, $4.80. London: Norman Rodger.

This is chiefly a descriptive book. The first part deals with filter construction. Filters with a loose filtering layer (open filters; closed filters; apparatus for reduction of iron from water; water softeners; the spirit filter), are first considered (thirty-five pages). A discussion (fifty pages) follows of filters with woven or flted filtering mediums (open filters; continuous action drainer-filter; bag or frame filters; Ehrenstein's pressure chamber filter; the filter press, its construction and different types). Brief chapters follow on filters with rigid filtering layer on separating apparatus without filtering layer, and presses for the separation of liquids and solids.

So far the book is essentially a translation of Bühler's German book and as such it should be welcome to American readers, though its usefulness is limited by the fact that almost exclusively German practice is considered. To repair this defect somewhat, the English translator has added some further chapters. First, a brief discussion on the theory of filtrations and a useful chapter of twenty-six pages on filtration in the sugar industry. In the latter a description is given of the Kelly filter press and the Sweetland filter press. The use of kieselguhr for filtering is dealt with at some length. Suction filters which have assumed such great importance in cyanide work in this country, are passed over with the remark that vacuum filters are not often used in sugar-house work because to filter rapidly the liquors must be hot, and when a high vacuum is applied, hot liquids begin to boil and thus destroy the vacuum. Descriptions of a few types of centrifuges are given, as they are essentially rotating pressure-filters.

For the list of German patents given in the original book of Bühler, a list of British patents covering the same subjects has been substituted (twelve pages), while in the section covering "Specifications of sundry filter press patents" (twenty-two pages) the text of the British specification has been followed where available. Otherwise the German version is reproduced in full.

The Silicates in Chemistry and Commerce. By Dr. **W. Asch** and Dr. **D. Asch.** Translated by **Alfred B. Searle,** with critical notes and additions. Large octavo (15 by 25 cm), xx+, 456 pages. Price, $6. New York. D. Van Nostrand Company.

The bulk of this treatise is based on a monograph prepared by the Doctors Asch upon the hexite-pentite theory of silicates. The basis of this is the assumption that six atoms of silicon with six atoms of oxygen form a closed ring having twelve free valences, or that six atoms of aluminium with six atoms of oxygen form a closed ring having six free valences. These are called "silicon hexite" and "aluminium hexite" respectively. Similarly, five atoms of each form, with oxygen, closed rings having ten or five free valences respectively, and called "silicon pentite" and "aluminium pentite" radicals.

From this starting point the authors attempt to explain the constitution and chemical characteristics of all silicates and alumino-silicates, along with many of their industrially useful physical properties. The attempt is most ambitious, painstaking and interesting, and gives many new points of view for the consideration of such subjects as the constitution and properties of clays, ultramarines, Portland cement, slags, porcelain cements, glass, enamels, porcelain.

The authors extend the principle to the study of complex salts of molybdenum and tungsten, and even devote a chapter to the consideration of the theory "as a general theory of chemical compounds," in which it is used to explain water of crystallization, metal ammonias, carbon compounds, and the constitution of the chemical atoms.

In the last section of the book the theory becomes the stereo-hexite-pentite theory, being considered stereochemically in order to combine it with the modern theory of the structure of crystals, and to explain polymorphism and isomorphism.

The work concludes with the tabulation of several hundred analyses of silicates and their comparison with the requirements of the theory.

It is difficult to characterize this tremendous piece of work in a few words. It is a mine of information on many unusual topics; it will be very interesting to the chemist and physicist, as possibly containing the seeds of many new discoveries and advances; and yet it is not convincing or altogether satisfactory. One feels that the authors have made a splendid presentation of their case, and yet leave this impression on the mind of their readers: "not proven."

Why Play to the Galleries?

It never rains but it pours. If it is not a new and revolutionary invention in oil chemistry, it is at least an announcement of one. And the daily newspapers seem to be happy that besides the war they have something else they can write about without being troubled by scruples that come from too much knowledge.

At the February meeting of the American Institute of Mining Engineers in New York, Dr. Walter O. Snelling presented in the Petroleum and Gas Section informally a paper on gasoline from synthetic crude oils, relating some surprising and interesting observations. The paper was discussed in open meeting. An abstract was published in our last issue. The formal paper in full will be published in the next *Bulletin* of the Institute.

A fortnight later, on the first of March (it was not the first of April) the daily newspapers printed a remarkable interview with Secretary Lane in Washington, on two now celebrated oil inventions of Dr. Walter F. Rittman of the Bureau of Mines, and in the string of delightful newspaper stories which followed, an American dyestuff industry was created on paper under the protecting wings of the Bureau of Mines.

It is a pity that no official technical information was given out at the same time. We hope that Dr. Rittman's expectations will be realized—whoever knows him likes him. But whatever the future may bring, it is like a blow to the standing of the American chemical profession that the announcement of achievements of such alleged importance should have been made in a manner so unconventional according to professional standards. Claims should not be made unless proof is produced at the same time. First with radium and now with oil, the Bureau of Mines has been rather unlucky in the choice of its press agents.

A Spectacular Spelter Market

The daily market report on spelter has made interesting reading for a couple of months. It was anticipated, of course, that spelter would rise after the war started and authorities freely predicted seven-cent spelter. The predicted price has been exceeded and ten-cent spelter realized. The explanation lies in the fact that our domestic production and consumption have been about equal; and with foreign production greatly curtailed a tremendous export demand has been added to domestic needs. Add to this a certain hysteria that is likely to accompany such conditions, and we have the explanation of a runaway market. The inevitable slump has come and prices have receded, but will probably remain high during the war.

A review of average annual zinc prices for thirty

years past shows that the highest prices at New York was roundly seven cents for 1912. Prior to that the high average was about six and two-tenths cents for 1906. In no other year was the average annual price as high as six cents. Present prices are without comparison. The highest price ever paid for Joplin concentrates was reached early in February, when the basis for 60 per cent concentrates was $70 per ton, with premium grades bringing a higher price. Utah and Colorado operators have taken advantage of the situation and have been shipping low-grade ores. Of course such conditions could not last long. They work temporarily to the benefit of ore producers, but are not so acceptable to smelters who have to buy ore at a high price with the prospect of being able to sell the metal therefrom at a time when prices have receded from their high level. It was for this reason that zinc-ore producers who were without smelter contracts found it impossible to sell their ores at any price.

Illuminating Pig Iron Statistics

The official statistics of pig iron production are presented in such detail that some interesting conclusions can be derived as to trade movements and the character of material produced from the iron. The production in 1914 was 23,332,244 gross tons, making the year's tonnage 24.6 per cent under that of the record year, 1913; 1.4 per cent under that of the lean year, 1911; but 46.3 per cent in excess of the tonnage in 1908. So rapidly has the iron and steel industry grown, however, that the 1914 output was greater than that of any year preceding 1906, even though 1905 in its time was a year of great activity, and the output was more than quadruple that attained in 1886 or any preceding year.

The banner year for the Bessemer process was 1906. In years of relatively full demand, like 1912 and 1913, the character of the steel process employed is necessarily dictated largely by the facilities available, while in a year of light demand like 1914 the preferences of buyers have more influence, hence the following comparisons between 1906 and 1914 are quite illuminating:

PIG IRON PRODUCTION

	1906	1914	Change
Bessemer	13,840,518	7,859,127	—33.2%
Basic	5,018,674	9,670,687	+92.8%

Included in the tonnage reported as "Bessemer" is about 200,000 tons of low phosphorus iron, the precise output of which in 1914 has not yet been separately reported.

Of the Bessemer and low-phosphorus pig iron produced in 1914, 5,467,687 tons, or 69.5 per cent, was delivered molten, indicating almost universal and continuous employment of direct metal, except as prevented by the necessity of casting Sunday metal and metal for stock, as well as the shipment of iron between works under allied ownership. Of the total production of Bessemer and low-phosphorus iron in 1914, only 527,905 tons was made for sale. Doubtless this comprised nearly all the low-phosphorus iron, the remainder being almost exclusively iron sold for the manufacture of ingot molds. The major part of this iron is delivered molten, although sold, and with two additional plants now being built to use direct metal in making ingot molds the vogue of this process will become practically universal, even though the ownership of the mold foundries is entirely different from that of the furnaces which, under long-term sliding-scale contracts, furnish the molten pig iron. In the case of basic iron 6,436,146 tons, or 66.5 per cent, was delivered molten, leaving 3,234,541 tons that was cast, doubtless all in chills. There was 1,479,721 tons of basic iron made for sale, and it is doubtless accurate to deduct this tonnage, as having been cast, leaving it that 8,190,966 tons of basic iron was made for the consumption of the producers, all but 1,754,820 tons of this having been used direct, making 78.6 per cent of the makers' production used direct, an even larger percentage than obtained in the case of Bessemer iron.

A Suggestion in Patent Reform

Previous comments in this journal on needed reform in the United States patent system have made it apparent that the objections to our patent procedure lie not so much in the organic law as in the methods of enforcement of the contract between the government and the individual. In the development of our system it has suffered from the same practices that have received public disapproval in ordinary court procedure. Legal technicalities have supplanted in importance the economic aspects of a case, and legal form and procedure have almost attained the dignity of an end instead of a means.

The abuses which have thus found their inception and growth in the practice of adjudicating patent rights have led to the suggestion of a special court of patent appeals with revised rules of procedure and power of final decision. Even this excellent suggestion, however, concerns itself with improvement in the system *after* the patent has been granted, and offers no relief from obvious deficiencies in the system prior to and including the actual grant. The point is that probably much of the trouble now following the grant of a patent might be obviated by greater care in the granting.

Under present conditions a metallurgical or chemical patent in litigation has not received the careful attention of experts until it is called in question. Then it becomes the subject of a long investigation, and expert testimony is brought forward in great volume. The question arises: If experts are deemed necessary to settle a point in litigation, might they not be of equal value in passing scientifically on applications for patent? If, instead of submitting a patent to experts after it has been granted, it were subjected to scientific examination before granting, the prospective patentee might be relieved of much expense, delay and trouble, and would not feel that he had been deceived as to the nature and value of the covenant between himself and the government. Hoover comments on this phase of the matter in his book on Concentration by

Flotation, saying that "if the courts deprive him (the patentee) of the benefits definitely promised, someone has blundered. Every legal case in which the patents of one litigant are declared invalid is an indictment of the most serious nature against the system."

Another benefit that might result from scientific examination of patent applications would be the rejection of many supposed novel ideas of alleged usefulness. Many of these are scientifically unsound and claim results that are practically impossible of achievement. They merely clutter the record. Others contain alleged improvements and are often introduced by patent pirates and leeches. It is recognized, of course, as Hoover says, that "a new metallurgical process never springs fully developed from the brain of one person," and consequently many of the improvements are valuable. On the other hand, one has only to review the patents and litigation in one subject, such as flotation, to feel that if scientific experts reviewed the applications, many of them might not be granted. The situation would be freer from complications and progress in the industry would not suffer.

The Steel Corporation's Operations

Probably there was nothing occult in the coincidence that the thirteenth calendar year of the United States Steel Corporation's existence proved to be its worst in point of earnings. The earnings, $71,663,615, were not only the lowest, but were only 44.5 per cent of the earnings reported for the Corporation's best year, 1907. Allotted per ton of steel products made the earnings were $7.95 per ton, thus falling below the previous minimum, $8.65 in 1912, and thus being but 48 per cent of the highest average shown, that for 1902, $16.59 per ton. Roughly speaking, the decrease in earnings per ton in twelve years has been approximately equal to the decrease in steel prices, but the Corporation's expenses, particularly in the average rate of wages and in the amount of taxes paid have greatly increased. These, apparently, have been offset by refinements in manufacture and by carrying the products, on the whole, to a greater degree of finish.

In 1902, with practically full employment of all the Corporation's manufacturing facilities, the output of steel products, weighed in the form in which sold, was 8,033,556 tons, while in 1914 the output of 9,014,512 tons is stated to have represented only about 62 per cent of the capacity, indicating an increase of about 75 per cent in capacity in twelve years, making the present capacity about 14,500,000 tons. During this time the bonded indebtedness, including bonds held in sinking funds, has been increased by $345,000,000, while the preferred stock outstanding has been reduced by $150,000,000, making a net increase of $195,000,000 in the securities, an increase of 14 per cent. The actual value of plant facilities, per ton of finished steel capacity, has been very greatly increased, partly through refinements in manufacturing, for the production of the same material, and partly through the addition of finishing departments to carry steel to a higher degree of finish.

The Corporation's output of by-product coke in 1914 was 4,081,122 net tons, or 36.5 per cent of its total coke output, the highest proportion in its history, and comparing with a proportion of 6.1 per cent in 1907, the first year for which by-product coke was reported. The tonnage of Bessemer steel ingots was by far the smallest in the Corporation's history, only 4,151,510 gross tons, the proportions of ingot production being 35 per cent Bessemer and 65 per cent open-hearth. In 1902 the proportions were 69 per cent Bessemer and 31 per cent open-hearth. The relative productive capacity, however, has not changed so greatly, as in 1902 both Bessemer and open-hearth facilities were fully employed, while in 1914 there was a larger percentage of idleness in Bessemer than in open-hearth departments. It is entirely pertinent to observe, however, that in 1902, with full employment of the facilities, the open-hearth ingot production was 2,984,708 tons, while in 1914, with light employment, the production was 7,674,966 tons. The Corporation's maximum production of open-hearth ingots was 10,524,552 tons, in 1913.

While the total output of merchant steel was 12 per cent greater in 1914 than in 1902, the production of rails was 49 per cent less; tubing and pipe increased 23 per cent; sheets and tin plates increased 52 per cent, and there was a large increase in sundry products.

High-Grade Ore

There is no more spectacular incident in mining than the discovery of high-grade ore. It commands public attention, stimulates activity in prospecting and leasing, and brings visions of sudden wealth to the stockholders. There is a more sober side to the matter, however, that becomes painfully apparent when such ore is marketed. What is its true value and how shall it be determined? And when the value is ascertained, how shall the precious stuff be treated with minimum loss? The sampling and estimation of the value of high-grade ore is not a simple matter. Discrepancies rapidly mount into the thousands of dollars. Buyer and seller are far apart in their estimates, each sure that he is correct. The difference is so great that the common ground of agreement seems hopelessly unattainable. Both sides "play safe," knowing full well the chances of loss in the transaction.

The recent discovery of unusually rich ore in the Cresson mine in the Cripple Creek district was properly a cause of more than local excitement; but it is safe to say that before it was marketed it was the cause of considerable worry. It was originally sampled at a local sampling works and consigned to a Denver smelter where it was again sampled. The results of the two samplings were widely at variance, the reported difference of opinion representing about $40,000 on the shipment. A resample was made at the smelter, and although the shipper's control sample checked closely enough with that of the smelter to have brought about a settlement, there was still the wide discrepancy with the original sampling. Buyer and seller could not agree and the ore was removed elsewhere for sale and treatment. There are some compensations in the steady production and treatment of ore of medium grade.

Readers' Views and Comments

The Radium Situation

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In your March number Mr. Warren F. Bleecker makes a very remarkable statement which should not be permitted to go unchallenged by the chemists of this country. "There were," he says, "in this country no men who could determine radium quantitatively with any degree of accuracy," referring to the time when the Standard Chemical Company first entered the radium field. By those who have followed the development of radium from the beginning, who recall that practically all our knowledge of the quantitative relations of radium and radioactivity is based upon the work of Rutherford and Soddy at Montreal, who are familiar with the exact work of Boltwood at New Haven and of McCoy at Chicago, this statement will be taken for what it is worth, but it will no doubt afford comfort and solace to those curious individuals who take pleasure in depreciating what is nearest them.

With the substance, however, of Mr. Bleecker's paper I most heartily agree. If the Federal government goes into the radium business on the plea of monopoly, why not into the nickel business, and the manganese business, and the bread business, and every other business? Surely the interference of governmental agencies in private affairs has gone far enough for an English-speaking country. Stewart J. Lloyd.

University of Alabama,
University, Ala.

* * *

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I thank Professor Lloyd for calling attention to the statement made by me relative to the accurate quantitative determination of radium. This statement is in error and I am pleased to correct it at this time.

A further explanation of the situation to which I referred is as follows:

During the time mentioned, which was in the years of 1910 and 1911, the founders of the Standard Chemical Company endeavored to obtain, in this country, the services of men of standing and authority, to measure and investigate radium in carnotite ores; and to one or more laboratories at least, samples of carnotite ore were sent for measurement and for advice as to possible extraction processes.

When it is realized that in the working out of a commercial process, the number of radium determinations upon the raw ores, intermediate and final products is very large and that there is a great variation in the kind of samples necessary for controlling the work, one may easily imagine that this work could not be well done within the limits of a university laboratory however skilled the operator might be in making a research in which he is not limited as to time.

We were taught in the early days that it was usually necessary, in making a determination of radium, to allow the samples to stand until the emanation had reached its equilibrium value, which is four weeks. In the control of a metallurgical process it is easily seen that this is out of the question.

While I am very glad to correct the statement, which, taken literally, is obviously incorrect and unjust, I wish again to call attention to the difference in the point of view between those who are doing academic work and those who are engaged in applying data and conclusions so obtained in a commercial way.

Industrial concerns must always look to the great men of our universities to supply not only information about new things, but also to train a fair proportion of their students as far as possible in technique, so that when called upon, as they surely will be, to meet a demand for men to apply these things, it can be met safely and without embarrassment.

I had this situation in mind without realizing that a general statement relative to our peculiar relations to the measurement of radium, might cast reflection upon those who were in the work and upon whose researches we now base much of our knowledge about radium, as has justly been stated by Mr. Lloyd.

While Mr. Lloyd does not necessarily imply that we are of "those curious individuals who take pleasure in depreciating what is nearest them," it is but fair to say that it was not until July, 1912, that we were able to obtain the services of any one who was willing to come to our laboratory who had at the same time the ability to turn out results satisfactory for commercial work.

Further than this, we had previously had a gentleman with us who, without casting reflection upon the institution from which he was recommended, was unable to meet the requirements of his position. The only time I was able to get a positive statement from him as to the quantity of radium in any ore or product was just before his departure. Then he specifically told me that a resulting tailings product contained more radium than the ore from which it came, illustrating that his sense of humor was inversely in proportion to his ability to measure radium.

Carbon Bricks for Plant Furnaces

To the Editor of Metallurgical & Chemical Engineering:

Sir:—Permit me to ask the readers of your journal if carbon bricks have been used as lining for common pig-iron blast furnaces, and if so, with what result?

It seems that such bricks of a good quality ought to serve the purpose rather well, as far as the bottom is concerned, judging from the results obtained in electric furnaces for similar purpose, where they have proved very satisfactory.

The material is cheap in comparison with some other refractories, and the wear and tear far less than what one should anticipate. Joh. Härden.

Guldsmedshyttan,
Sweden.

Comparisons of Electric Resistivities at High Temperatures

To the Editor Metallurgical and Chemical Engineering:

Sir:—In my article on the above subject in your January issue, Charts 1 and 2, page 24, there is an error in the curve for platinum. It is only in the exterpolated part, and as no values exist, the error is not important, but the figure nevertheless should be corrected.

Platinum melts at 1755 deg. C., and the figure for that metal should, therefore, rise abruptly and vertically at that temperature. No determinations, to my knowledge, have yet been made of the increase in resistivity of platinum at its melting point, nor even to show that it does increase; but presuming that it does, and assuming that, like most metals, the resistivity approximately doubles when the metal melts, the curve for platinum in Charts 1 and 2 should have been drawn accordingly. As this curve is merely exterpolated for

quite a wide range below its melting point, this correction is necessarily only very crude, though it seems to be the best information existing at present.

Philadelphia, Pa. CARL HERING.

Chemical Engineering Versus Engineering Chemistry

To the Editor of Metallurgical & Chemical Engineering:

Sir:—What's in a name? Perhaps but little; nevertheless, the writer, for one, has had some difficulty in seeing the difference between the two lines of activity implied in the title; and there are others at present who do not seem to realize that there is a difference. When I was a teacher of "pure" chemistry, the difference was not clear. When I had some of the hard, grueling experience of the University of Hard Knocks, I came to see what the difference is, and how tremendous it is.

Only recently I was asked, and by one of the prominent educators of the country, what is chemical engineering? To cut matters short, I told him that chemical engineering is industrial chemistry, which seemed to satisfy him; but, strictly speaking, the answer is by no means true. It is true that theory and practice in chemistry may merge into each other so that it is or may be hard to discriminate, at times; but in the large sense, chemical engineering ought to be more than engineering or industrial chemistry. But let us take an illustration.

The manufacture of sulphuric acid by the contact process, or rather by any one of them, can be worked out in the laboratory of pure chemistry. We may ascertain the substances involved in the special reactions used. We may test out the results by careful quantitative work. We may even go so far as to plan the design of commercial works for this process. We may be able to make some provisional and tentative estimates of costs and expenses. All this is good; it is essential; but it is only industrial or engineering chemistry.

The well-planned process becomes chemical engineering, only when it is carried over to the actual manufacturing conditions and results. Then there appear conditions which must be unknown to small dimensions and crude conditions of the experimental laboratory. When one enlarges apparatus from test-tube-and-beaker to small commercial size, there invariably appear new conditions and new troubles, unguessed and undreamed of at the earlier stage; and when one advances from small commercial size to true generous commercial dimensions, then other new and more vexing problems appear to be studied and solved on this large-scale plant. All this is so well known to the experienced engineer that it may seem not worth mentioning; but this common truism is not known, nor properly appreciated by the educators who are just waking up to the problems of establishing schools of real chemical engineering. I presume that it is something which can come only from hard and bitter experience—this realization of what engineering is, as distinct from the theory of what it ought to be, or might be. It seems to be what each one must learn for himself.

At what then shall the teacher of chemical engineering aim? It will be a safe theory to follow, to assume that the schools should try to give the student both the foundations, and also the immediate connections of these foundations with actual practice. I assume that the student has been given good and long training in the various branches of chemistry, together with the essentials of physics, mechanics, the "handy" acquaintance with mathematics, depending on his special aptitude in that much abused necessity, the basis of drafting, materials and this especially, a practical reading familiarity with French and German, and command of writing his ideas in commonsense English. But all this is only the preparation for the actual struggle now to come, the mastery of the principles of chemical engineering, and the practice of the chief processes involved in their application. Now it is easy to enumerate some of the eternal chemical processes; they include solution, mixing, precipitating, filtering, drying, conveying, distillation, etc.

Let us take the old process of filtering for example. The student should be required to take down, inspect and reassemble any one of the good old types of filter-press. He should be given the same course with some of the newer types, such as the remarkable Sweetland filter-press, which has been described in the pages of *Metallurgical and Chemical Engineering*. He should be taught to look out for new and progressive attempts to solve the problem of continuous filtration, illustrated, for example, by such a machine as the "Filtros" continuous filter, described on page 125 of the February, 1915, issue of this journal; and he should do it by means of a specimen of the new machine large enough to show its commercial use.

In all this the student must inevitably run across the business questions of power, labor, wages, etc., and he must be shown how to incorporate all this in his estimate of the special suitableness of the various types of filters for the special problems to be studied. And in deciding what is the best machine for the special material to be treated, there is no better rule than that of Mr. Edison, "If you want to find out a thing, try it."

And so on, with all the chief chemical processes—each must be studied with enough equipment to show what is being done, and what improvements are needed and possible.

But what of the fundamental chemical and mechanical principles involved in chemical engineering? What of the production; the transference; the use; the measurement of heat, electricity, power; what of all these? It goes without saying that they must be mastered, but would it not be well to have the student always master them in connection with the construction and use of some special machine or process? In this way the student will always have his attention focussed on the commercial use of his materials and methods.

But what of the questions to be faced in the title of this paper? What of the relations of engineering chemistry on the one hand, with chemical engineering on the other? I presume that for the schools of one kind it may be well to teach directly certain trades, such as dyeing, tanning, soap-making, sugar refining and the like. There is a call for young men so trained; and some of our most helpful schools, as the Pratt Institute, do such work, and do it well.

But for the higher type of graduate engineering, it may be well to query whether the best results will be reached by the special training in special trades. Here it would seem that the very thoroughness involved will show that the most and the best can be done by training, practical training, in both the processes and the principles involved and implied in the application of the laboratory to the factory. But this demands large equipment in power, buildings and machines, not to speak of the implied laboratory and shops accessory thereto.

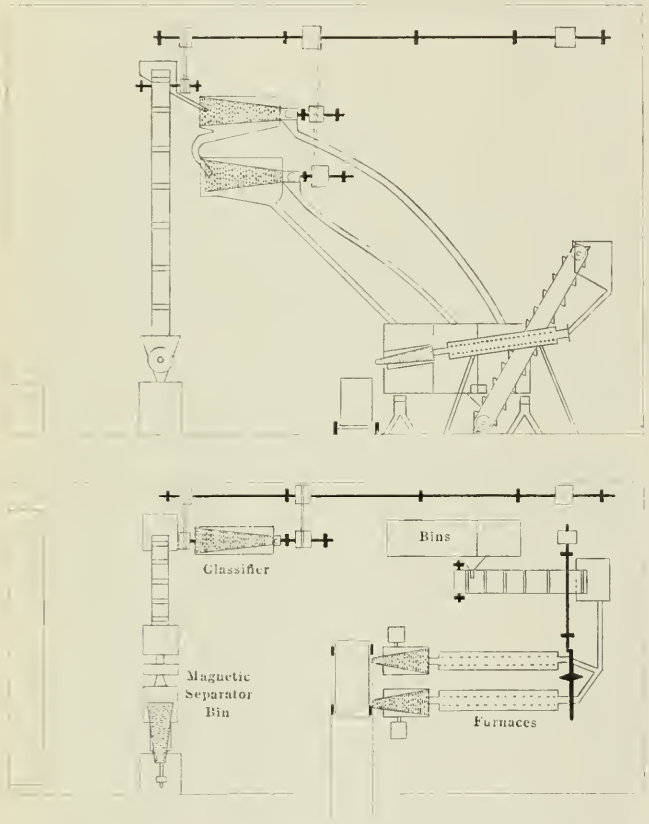
And this brings us to our conclusion, namely, that the chasm between engineering chemistry and chemical engineering must be closed up as fast and as thoroughly as possible. Not that it can ever be entirely bridged over, but the gap can be lessened and, by dint of wise and persistent effort, we may be able to put and keep the young enthusiast in closer touch with the engineering idea: "Go as far as you can see; and then see how far you can go." CHARLES S. PALMER.

Newtonville, Mass.

Separation of White Metal and Gunmetal Borings

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In locomotive machine shops there is produced a large quantity of gunmetal borings mixed with white metal, which, in certain cases, is very difficult to deal with. So far as we are aware the only method used for effecting a separation is liquation on an iron plate or in a furnace. This process is only suitable for coarse borings and absolutely useless for the finer grade material. Owing to the rapid accumulation of fine borings in the New South Wales Railway workshops it was necessary to devise a scheme for the recovery of these two classes of metal and keep them in circulation. This metal cannot be smelted straight out and used generally for castings on account of the high antimony content—0.6%. It could, perhaps, be used for a few special castings, but for general railway purposes, a mixture of this kind would probably soon lead to serious trouble.



ARRANGEMENT OF PLANT FOR THE SEPARATION OF WHITE METAL FROM GUNMETAL BORINGS

Under present conditions the borings taken from the machines are shaken on a ¼-inch mesh sieve and the coarse white metal separated from the gunmetal by liquation on an iron plate. The removal of the white metal in the fine borings is the problem we were asked to solve.

After a few experiments it was decided to pass the small borings from bin to a magnetic separator, pick them up by revolving belt fitted with pockets, and convey them to a bin above classifiers. From this bin the borings gravitate to classifiers and are separated into three grades. From bins Nos. 1 and 2 containing the coarser material, the borings gravitate on to a short revolving belt fitted with pockets and are delivered into a bin above the furnaces and here gravitate to the furnaces. These furnaces are constructed of iron tubes, one fitting inside the other. The outer one being several inches larger in diameter than the inner one, is supported by means of brackets to the floor and carries in the intervening space between the two tubes, a coil of iron pipe with suitable size perforations for heating the walls of the inner tube by gas. The inner tube is revolved and the hot borings and liquid white metal pass into revolving screens smaller in mesh than the last classifier, and the liquid white metal mixed with the borings allowed to escape through the screen into an outer vessel surrounding the screen, and which is heated by a gas coil. In this way the white metal does not cool, but collects at the bottom and can be run into moulds.

The clean borings pass along the screen into a hand truck on wheels, which can be taken to the foundry and the borings smelted and utilized for ordinary gunmetal castings.

The finest grade in No. 3 in., which is only a small percentage of the total, will probably have to be smelted and the bulk of the antimony got rid of by oxidation.

The sketch herewith shows the arrangement of the scheme suggested for the treatment of the above class of material at the railway workshops.

Tube-Milling in All-Slime Cyanide Practice

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I am much indebted to Mr. Haynes for putting in concrete form much that I would like to have said on closed-circuit tube-milling. As he shows, the cumulative load going to a tube-mill makes a preposterous proposition if the original load is more than the tube can grind. If it cannot fully grind the original 100 tons of battery pulp, it cannot grind 67 tons of return feed plus another 100 tons of new pulp.

It is contrary to all logic to overload any machine and then return the untreated part to the same machine. We went through that experience when the Wilfley and other concentrating tables came out. Every table was equipped with a return elevator for middlings. What became of those elevators? They promptly went to the scrap heap; and the solution of the middlings problem was found in separate treatment, regrinding and retreating on separate tables. In cement factories we find large tube-mills used. Do they use "closed circuit" or "open circuit?" Has it not been fully determined in roll-crushing plants that small sizes must be eliminated and sent to other rolls, and that it is not economy to grind several sizes in one machine? We see in Mexico that even in crushing for the making of *tequila* the fresh material goes to the first set of rolls and the partly crushed stuff to a second set. In fact, is it customary in any mechanical work of this kind to return an unfinished product to be treated with fresh material?

We then come back to the possible claim that the partly ground sand from a tube-mill is so easy to finish that on its return to the tube it is properly ground during the second cycle. If so, it shows that it would be better to work tube-mills in series, as quoted by Mr. Haynes in referring to the Liberty Bell mill. Sufficient tube-mill capacity has to be provided to do the required work, and I believe it will require more tube-mills to do the grinding in closed circuit than in open circuit in series, with an intermediate classifier. Indeed, I think that the work can be done with tubes in parallel, with open circuit, feeding a pulp of low-moisture content. I think that high-discharge mills necessitated high moisture; high moisture made poor grinding; poor grinding occasioned the return of unground pulp, and the return was wrongly made to the same tubes instead of additional ones. A tube-mill should have all the neces-

sary elements wherewith to grind in one cycle to the required degree of fineness. The varying positions of the ore particles with reference to the diameter of the mill, and the many sizes of pebbles in the charge, furnish a multitude of grinding conditions to fulfill all requirements. A tube-mill will grind new feed plus return pulp if the conditions be right; but it can grind only so much ore and an overload results in poor work.

A point that I have observed in tube-milling is that on feeding coarse mine rock for pebbles, the angular projections or corners are broken off quickly and accumulate in excess of the quantity required to fill the insterstitial spaces. They then discharge through the screen plate at the tail of the mill and if fed back by hand they continue to be discharged, since they form a cumulative load that the tube cannot grind. They must be taken up to the batteries in order to successfully dispose of them. When flint pebbles are used for grinders this condition does not exist, as the pebbles wear only in proportion to the grinding done. In fact, if a tube is started with large pebbles only, it will do very poor work until a sufficient number of small pebbles form to fill the voids.

Although not wholly pertinent to the discussion, I want to comment on the custom we have of referring to fine grinding in terms of "per cent through 200-mesh." It is an arbitrary and indefinite term, particularly because it gives no clue to the degree of fineness to which the whole pulp is ground. It tells nothing about the fraction that is not ground through 200-mesh, and very often it is this fraction that influences final extraction. If this fraction passes 150-mesh and the extraction is satisfactory, it would be better to use the term 150-mesh for the whole. If the fraction passes 150-mesh and the extraction is not satisfactory and can be made so only by grinding to 175 or 200-mesh, then that term should be used. In short, the practice of referring to "per cent through 200" leaves us in the dark regarding the coarser portion which, while it is not mentioned, may be the critical feature of the grinding.

I recall one plant in which we were treating 1000 or more tons daily. The final pulp going to the treatment vats averaged from 67 per cent to 70 per cent minus 200-mesh. The plus 200 caused poor extraction, occasioned high cost and stuck up the vats. Without changing the crushing and grinding equipment, we modified the classifiers and fed 30 per cent moisture pulp to the tubes. Classification was greatly improved, extraction increased, costs came down and no further trouble was experienced with the ore in the vats. Eighty per cent of the ore passed 200-mesh, and we still spoke of our grinding in terms of that figure. Would it not have been more significant if we had expressed our former grinding as 120-mesh and the latter as 175-mesh, rather than 68 per cent minus 200 and 80 per cent minus 200, respectively.

Guadalajara, Mexico. W. J. PENTLAND.

Grinding Ore for Cyanidation: A Suggested Modification for All-Slime Practice

To the Editor of Metallurgical & Chemical Engineering:

SIRS—I have been gratified to see that my contributions to the discussion of cyanide practice have evoked some comments, as shown by the articles of Mr. Pettis and Mr. Haynes in your January number. I am sure that a good deal has been overlooked in general practice by the failure to treat distinct parts of the ore according to their particular conditions or needs. It was not my intention to suggest or formulate a procedure applicable to all ores, but to call attention to the feature of giving particular treatment to different parts of the same ore.

The subject offers a large field for discussion. We have first the probability that there has been too pronounced a tendency to rush to all-sliming, overlooking the possibility that it might be advisable to leach all the sands, coarse and fine, or that the fine sand might better have agitation with or apart from the slime, and only the coarse sand leached.

The matter of removing concentratable material, either because of its injurious effect in consuming cyanide, or because it requires more elaborate treatment, has usually been duly investigated; but further investigation into the subject of segregating other parts of the ore has generally been overlooked, although the nature of the problem is the same.

My attention has been called to this subject by the experience of many mining companies in Mexico. Most of them began operations with ordinary battery crushing, concentration, slime agitation and sand leaching. The concentrates were shipped to smelters or cyanided separately. All sliming then came into vogue; slimey and sandy gangue matter yielded to agitation, but the old question regarding concentrates still survived. Most of the operators came to the conclusion that it was more economical to abandon concentration and to slime everything. This was a decided move in opposition to the idea of special treatment for different parts of the ore; but as any gain in ultimate economy is the final deciding factor, the change was to that extent an advance in method of treatment.

Many of these plants are now agitating for 48 hours, using 6, 7 or 8-lb. cyanide solution. Such treatment probably is called for by the concentrates and coarse sands, even though quite finely ground, and so all the ore receives the maximum treatment. Nevertheless, I believe that an advantage might be found in making a separation at the classifier, providing separate treatment for the slime and for the sand with accompanying concentrate, perhaps combining the two portions at some later stage after the sand and concentrate had received special treatment. Continuous treatment methods make many things possible that were impossible with intermittent methods. It would be quite a different matter to provide stock or storage tanks in which to accumulate several different kinds of pulp for subsequent treatment by an intermittent process.

Arrangement of plant for agitation of two products is not so complicated as might be thought. Suppose that slime and sand each comprise 50 per cent of an ore and that four agitators are in use. The slime from the classifier could flow direct to a thickener and thence to the last two agitators. The sand discharged from the tube-mill could flow through the first two agitators and then to the thickener, from which the combined pulp could then pass to the last two agitators. Thus the sandy portion would receive double the agitation of the slime. This scheme does not contemplate closed-circuit tube-milling; but for those operators who prefer that method a primary and secondary classifier would be necessary in order that the tube-mill discharge could be classified without mixing with fresh battery product.

Under this scheme, standardizing of agitating solution could be made where it would do the most good.

If it were desirable to separate coarse sand for leaching, that could be done by classifying the tube-mill discharge. If it happened that the slime were the part requiring more extended treatment, the system could be arranged accordingly.

It would, indeed, be strange if the cyanide process should prove to be the only method of ore-treatment wherein it were found desirable to treat the whole ore as one product rather than as two or more. In smelting we go to extremes in the mechanical handling of ores; smelting some just as they come from the mines; treat-

ing others by roasting, sintering, briquetting or other appropriate processes; recovering and re-treating flue-dust and other by-products. In concentration we classify and size without end, and regrind and reconcentrate middlings. And yet cyanide operators sometimes try to do the whole thing in one operation, on the assumption that the simpler the process the more economical. Is not too much being expected of that simple solvent, cyanide?

All-sliming of concentratable ores and agitation of the total ore as one product, undoubtedly gave better economical results than did concentration, slime agitation and sand leachings, or the plants would not have been changed. But did not the operators go one step too far when they decided to agitate all the products together, making the conditions of treatment for the most refractory part be guide for the whole ore?

Guadalajara, Mexico. W. J. Pentland.

The Danger of Throwing Inventions Open to the Public

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The public press now teems with statements regarding the new inventions and developments of Dr. Rittman and their importance. The announcement is made that these discoveries, after patenting, would be thrown open to all. This, if true, does not offer much hope that they will be adopted and developed for the reason that the value of a patent usually or at least often lies, not in establishing a monopoly in the patent itself, but in the incidental protection it affords to those who do the missionary work, that is the effort and money expended in developing it and making a market for the product.

It has already been stated that about the surest way to prevent the development of a new invention or process is to throw it open to anyone who chooses to practice it. If any competitor may adopt and use the means and appropriate the knowledge gained in developing an invention and marketing its product one seldom feels disposed to embark in the work, but if he does, then he must generally conduct it as a secret process if any suitable profit is to be expected.

It is a long way and one not often traveled from the conception of a truly original invention or even from the issuing of a patent therefor, to a profit from its use. If it is what might be called a secondary invention representing a minor advance in some article or method already commercially established the case is of course different and the invention may be in full use before the patent is applied for.

What the public wants is for meritorious inventions or improvements to be made and then put to use. An invention to be adopted must offer a substantial increase in value or service over what has occupied the field it aims to work in, and if the inventor gets for himself even a small fraction of the increase or saving which results, he is fortunate. His share will never be great enough to deter anyone from working the improvement.

If Dr. Rittman's inventions work in with the established methods of parties doing business in the allied lines, they may, of course, be taken up by such parties, but if they are of revolutionary character then the encouragement for their development and working, without protection, becomes small. Old business is naturally conservative, and a new invention which threatens if adopted to "scrap" existing plants, wholly or in large part, will usually be unwelcome until possibly its acceptance is forced by the march of events. The working up of the revolutionary invention must then be undertaken, if at all, by newcomers in the business with the chances against success.

Dr. Rittman might therefore promote the general good better and induce the introduction of his inventions quicker if he remains in position to afford pioneers in their development such protection that those who lie low waiting for others to show the way would not be able to come in later and reap where they had not sown. The only way for him to do this is to retain the patent rights for himself, or his assigns.

In this connection it might be said that if some legal way existed by which a business enterprise which develops and produces new goods could be protected from unfair imitation and competition when patent protection cannot be obtained, it would seemingly inure to the advancement of the arts and the public welfare. A new thing is not necessarily patentable.

Plainfield, N. J. Henry D. Hibbard.

The Western Metallurgical Field

Smelter-Smoke Litigation in California

The vagaries of smelter-smoke litigation are well illustrated in some of the cases that have hampered the smelting industry of California. In Shasta county, in the northern part of the state, the farmers succeeded in closing all the smelters except that of the Mammoth Copper Mining Co., which continued in operation under a system of neutralization of acid gases, and bag-house collection of dust and fume. By the method employed, which was described in Metallurgical and Chemical Engineering for December, 1914, the company was enabled to keep within the terms of the court decree relating to the composition of discharged smoke. Farther south, in the vicinity of San Francisco, the Selby Smelting & Lead Co. finally had its troubles satisfactorily adjusted through a commission, which found that the terms of the court decree were being substantially complied with. During the troublous times for these companies, however, the Penn Mining Co., operating a copper smelter at Campo Seco, in Calaveras county, was left undisturbed. Apparently its time has now come, for no fewer than 35 suits are reported to have been filed against it by the farmers in the immediate vicinity.

Some time since California had a state commission, appointed by the governor, to investigate the smelter-smoke situation. In their report, made about the end of 1914, they found that conditions around the Mammoth smelter were unfavorable, despite previous judgment to the contrary; but no strikingly unfavorable report was made as to Campo Seco and the Penn company. Hence, the latest developments are strangely unaccountable. The federal court has within less than a month again denied an injunction against the Mammoth company, in which the farmers alleged a violation of the decree; and since the first of this year 35 suits have been filed against the Penn company. Evidently the state commission, the federal court and the farmers are not in accord. It is rumored that covetous lawyers have stirred up the trouble among the hitherto satisfied farmers around Campo Seco, and have piled up suits for damage aggregating over $300,000, expecting to make their fortune through contingent fees. The scheme is old and moth-eaten. It worked in the early days of smelter-smoke litigation, when the smelters compromised and paid for real and alleged damage until the condition became unbearable; but it can scarcely be taken seriously in this day of scientific investigation of such damage. Such suits cost tremendous sums of money, requiring the services of many experts; and it is safe to say that smelters probably are much better posted as to genuine damage caused by smelter smoke than are a

group of farmers misled by lawyers. When the latter learn what it costs to secure the necessary testimony to support their cases, interest in the contingent fees is likely to wane.

Reduced Shipments from Cobalt in 1914

According to figures prepared by Mr. A. A. Cole, mining engineer for the Temiskaming and Northern Ontario Railway Commission, the bullion shipments from Cobalt, Ontario, during 1914 amounted to 9,624,629 ounces of silver, valued at $5,254,097. Compared with the shipments for 1913, there was a decrease last year of about 200,000 ounces, due mainly to disturbances in the mining industry caused by the war. The decrease in value of the 1914 output as compared with that of 1913 was about $600,000, due to the low price of silver prevailing during the last year. The Nipissing company contributed nearly 75 per cent of the total bullion output, amounting to over 600,000 ounces; but this was lower than for 1913 by nearly 230,000 ounces. The Buffalo company was second, with a total of over 900,000 ounces. This also was lower than for the preceding year, as the company operated only for the first seven months of the year. On the other hand, the Dominion Reduction and O'Brien companies showed substantial increases over 1913, as did also some other companies. Kerr Lake showed the greatest increase, producing over 400,000 ounces in 1914, as against 50,000 in 1913. The following list gives the shipment and value of bullion as compiled for 1914 by Mr. Cole:

Company	Ounces	Value
Bailey	1,353.95	$785.27
Beaver	9,849.00	5,004.09
Buffalo	912,250.00	500,013.35
Casey Cobalt	2,566.64	1,343.72
City of Cobalt	27,341.64	15,523.75
Cobalt Comet	1,597.54	923.65
Cobalt Townsite	36,538.86	19,580.17
Crown Reserve	626,374.00	343,822.52
Dominion Reduction	726,397.85	405,885.50
Foster Cobalt	2,157.13	1,017.62
Hargraves	794.00	414.81
Kerr Lake	407,238.53	183,970.15
La Rose	55,365.48	29,066.87
McKinley-Darragh	17,470.00	10,016.55
Nipissing & Customs	6,299,677.75	3,469,526.13
O'Brien	452,822.00	243,933.91
Penn-Canadian	16,454.94	8,839.69
Temiskaming	6,163.70	3,553.20
Toownsite-City	17,640.35	8,465.83
Trethewey	4,576.04	2,409.86
	9,624,629.40	$5,254,096.64

In the latter part of February the Nipissing company made one of the largest shipments of bullion in its history. The consignment comprised 320 bars containing 376,709 fine ounces of silver, valued at $183,645. The shipment followed the period of annual clean-up at the mills, and brings the total bullion shipments for 1915 past 1,000,000 ounces. Ore shipments from the Cobalt district, however, were low during February, amounting to only 995 tons of ore and concentrates. This is the lowest monthly shipment in seven years, and is also the first in which the monthly shipment has fallen below the 1000-ton mark. The decrease is ascribed to shortage of power during the month.

Progress with the cyanide plant annex to the concentrating mill of the Cobalt Reduction Company is being rapidly made; the building has been completed and the cyanide machinery is being installed.

Anaconda and Butte-Duluth

It is reported that the Anaconda Copper Mining Co. has failed to exercise its option on the mining and metallurgical property of the Butte-Duluth Mining Co. The failure to exercise the option seems not to have interfered with further negotiations with new interests, and it is announced that a new 60-day option has been given another concern. Anaconda is reported to have found the mine and leaching plant satisfactory, but disagreed with Butte-Duluth on the terms of sale.

Federal Mining Experiment Stations

The bill to establish ten mining experiment stations in the mining states, for the purpose of making investigations in the interest of better metallurgy, passed both houses of Congress and has been signed by the President. As no appropriation was provided in the bill, its terms cannot be put into effect at this time.

Company Reports

The report of the **Arizona Copper Co.** for the year ended September 30, 1914, shows a production of 38,942,455 lb. of copper, compared with 34,230,000 lb. for the previous year. Due to the lower price received for copper in 1914, the profit fell off over $700,000, a considerable proportion of which is directly attributed to the outbreak of the war. Drastic reduction in output was made directly following declaration of war, but in view of the recent improvement in demand, the production has been increased since January 1. Dividends for the year amounted to about $645,000. The sulphide concentrating department handled 932,945 tons of concentrating ore. The average ratio of concentration was 8.42:1. No. 6 concentrator was enlarged during the year and now has a capacity of about 3000 tons in 24 hours, but is not now running full time. The oxide concentrator and leaching plant treated 87,875 tons of ore, producing 5414 tons of concentrate, which was sent to the smelter. The leaching plant handled 72,649 tons of tailing.

The sulphuric acid plant supplied the leaching plant with 2937 tons of acid. Including ore treated at the old smelter during the first quarter, there was smelted 182,873 tons of ore and concentrate. The average yield of copper from this material was 10.65 per cent. The new smelting plant is reported to be working satisfactorily.

Butte & Superior Copper Company's report for the fourth quarter of 1914 shows the following operating data:

	Fourth Quarter	Third Quarter
Dry tons of ore milled	33,520	100,600
Average zinc content (per cent)	19.4538	18.582
Average silver content (oz. per ton)	8.9286	8.6359
Zinc concentrates produced (pounds)	20,464,000	60,974,968
Average zinc in concentrates (per cent)	53.947	54.32
Total zinc in concentrates (pounds)	11,039,557	33,121,312
Average silver in zinc concentrates (oz. per ton)	23.54	24.15
Mill recovery (per cent)	84.65	89.14
Mining cost per ton	$3.288	$3.201
Milling cost per ton	$2.466	$2.049
Total cost per ton, mining and milling	$5.754	$5.25

The low tonnage and production for the fourth quarter were due to closing the mill from October 17 to December 17. During this period extensive repairs were made and considerable remodeling done in the mill. Seven new cells were added to the flotation plant. The financial statement shows profit of $130,537.

The Trethewey Silver Cobalt Mines, Ltd., produced during the calendar year 1914 a total of 527,097 oz. of silver, valued at $251,843, as compared with the 1913 production of 619,429 oz., valued at $333,611. Ore reserve is estimated as equivalent to one year's production. The average price received for silver in 1914 was 6.08 cents lower than for 1913. The mill cost was $1.31 per ton, being 15 cents lower than for 1913. Shipments comprised 298 tons of concentrates averaging 1577.7 oz. silver per ton and 314 tons averaging 217.78 oz.

The Crown-Reserve Mining Co., Ltd., shows in its annual report for 1914 a production of 1,425,320 oz.

silver of a gross value of $740,092. On account of the low price of silver and the war the receipts were probably $100,000 lower than the same quantity of bullion would have produced in 1913. The milling record shows the treatment of 31,347 tons of ore, from which an average of 15 oz. per ton was returned. The total cost per ton was $4.16. The average value of high-grade shipping ore was $3,474. The cost of producing silver per ounce was 28.95 cents and the profit 22.97 cents. Dividends paid amounted to $424,515.

The Porcupine-Crown Mines, Ltd., which is controlled by the Crown-Reserve company, shows a production of gold during 1914 valued at $691,394 from 40,857 tons of ore of an average value of $17.65 per ton. Referring to mill operations, the report states: "The continuous decantation process has not only been justified but has proved remarkably adapted to the ores of the Porcupine district and, with one exception, has been adopted by all the important mines in the district. The average extraction of the mill for the year was 97.26 per cent." The cost of mill operation is given as $1.31 per ton. The estimated value of ore reserves is $1,500,000. Dividends paid amounted to 12 per cent, or $240,000.

The Non-Ferrous Metal Market

The general state of the non-ferrous metal market during March was one of confusion and uncertainty. Spelter continued its phenomenal rise to a point of collapse, but copper, lead and tin were firmer. The price of tin advanced decidedly, owing to scarcity of foreign supply.

Copper.—A good demand has existed, especially among domestic brass manufacturers, and the market is considered in a fairly strong position. During the early part of the month the price rose to 14.75 cents per pound, New York, with the prospect that it might go higher.

Lead.—Although domestic demand has continued rather light, foreign consumption is rather heavy and large shipments have been made abroad. The A. S. & R. Co. raised its price to 3.90 cents on March 1 and to 3.95 cents on March 5. The latest St. Louis quotations were 3.87½@3.92½.

Tin.—Prices varied widely at the beginning of the month, rising as high as 48 cents. Domestic demand was slack and the advance in price was ascribed to anticipation of shortage of supply due to disturbance in the shipping situation. Following the rise, prices fell to about 45 cents, New York.

Spelter.—The spectacular advance in this market apparently culminated early in March, and although prices have not yet become settled they are on the decline. Metal for prompt delivery was scarce and brought fancy prices. Metal for June delivery was offered at 8 cents. The nominal New York quotation last available was about 7.75@8 cents; St. Louis, 7.60 @7.75.

Other Metals.—Quotations for aluminum continue about 19@19¼ cents per pound, New York. A shortage in antimony again raised prices, different brands bringing from 21 to 27 cents per pound. Quicksilver also is up, $65 being paid for flasks of 75 lb. at New York and $60 to $63 at San Francisco.

The New York Section of the American Institute of Mining Engineers will hold its next meeting on Wednesday, April 7, at the Machinery Club, 50 Church Street. Dinner will be taken at 6.30 and afterwards a discussion will be held on the economic side of safety and sanitation as applied to the mining and metallurgical industry.

The Iron and Steel Market

At the close of March the steel mills were operating at an average rate of fully 65 per cent of their ingot capacity, though naturally at a somewhat lower rate measured in terms of finishing capacity, as finishing capacity always exceeds steel-making capacity. The average rate in March was close to 65 per cent, against about 55 per cent in February, 45 per cent in January and 35 per cent in December. The improvement in trade opinion of the prospects, what is commonly denominated in market reports the "sentiment," began about the first week in November. The improvement in buying began in December, while the increase in production began about January 1. The improvement has been continuous. In March the increase in orders placed and in the rate of production was relatively slight, while the improvement in "sentiment" was decidedly marked. This decided improvement in the trade's hopes for its future was due chiefly to recognition of the fact that when a steel-trade improvement has lasted over a period of about four months it is entitled to a great measure of respect. The little spurts to which the trade has grown accustomed in recent years have been matters of a couple of months.

The alignment of demand for steel products has been quite abnormal. It is a remarkable thing to see the steel industry operating at practically two-thirds of its capacity when scarcely any railroad material is being made and when there is very little structural work in progress. In certain branches of the finished steel trade there has been almost full employment. The tin plate mills have operated at about 85 per cent of capacity in the past three months, substantially as heavy a rate as has ever been seen in a first quarter. The wire mills, with a very fair domestic demand and with an abnormally large export demand, have operated almost at capacity in February and March. The pipe mills have had nearly a full demand for standard pipe, while demand for line pipe has been only fair, and demand for boiler tubes and oil country goods has been extremely light. Less than 10 per cent of the total steel produced in March was for eventual railroad consumption, whereas the average of the past few years has been 15 to 20 per cent and in earlier years the proportion of railroad steel was still larger.

A detailed scrutiny of the steel market indicates rather plainly that there is no prospect of any decrease in demand from the rate of the past month, while there may easily be a slight increase merely from seasonal conditions. For any decided improvement over present conditions one thing is absolutely necessary, and that is a loosening of funds for permanent investment in railroad extensions and betterments and in bridges, buildings and manufacturing extensions of various sorts. The demand thus far experienced, apart from the export demand and the demand for shipbuilding material, has been confined almost exclusively to materials for common everyday consumption for wire and tin plate, for instance, as contrasted with rails, steel car material and structural shapes. The latest thought in the steel trade, which is strengthening the favorable views entertained for the future, is that there may be within a few months a loosening in investment funds through anticipation of an early termination of the European conflict.

Pig Iron

One of those movements for which the Buffalo pig-iron market is becoming noted occurred late in March, a total of perhaps 150,000 tons of Buffalo iron being sold for second quarter and later delivery, at an average of about $11.75, f.o.b. Buffalo furnace. Apparently,

however, the movement was not due so much to a change in fundamental industrial conditions or to the buyers taking the initiative, but rather to the sellers dropping their prices and indicating that it was necessary for buyers to act promptly. After the Buffalo movement of last November, at about $12, the furnaces advanced prices about $1 a ton and have thus had room lately for making reductions. Other markets which had fair sales at that time did not advance and thus there are no facilities for arousing the interest of buyers in such markets. Apart from the Buffalo movement the pig-iron market continues dull and colorless—disappointing indeed since a large volume of contracts should expire April 1 while the evidences are that the tonnages have not been taken out as rapidly as the contracts contemplated. The market is quotable as follows: No. 2 foundry: Delivered Philadelphia, $14; f.o.b. furnace, Buffalo, $11.75 to $12; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13; f.o.b. Birmingham, $9.25 to $9.50; f.o.b. valley furnaces, 95 cents higher, delivered Pittsburgh: Bessemer, $13.60; basic, $12.50; No. 2 foundry, $12.75 to $13.25; malleable, $12.75; gray forge, $12.50 to $12.75.

Steel

After a period of extreme inactivity some inquiry for billets and sheet bars developed late in March, for second quarter, and slightly higher prices were quoted than had been nominally in vogue for prompt shipment, about $18.50 for billets and $19 for sheet bars, f.o.b. maker's mill, Youngstown. There is practically no market being made in Pittsburgh, and the delivered Pittsburgh price is about a dollar a ton above the Youngstown basis. Deliveries on contracts were much heavier in March than in February. Rods are $25 to $26, Pittsburgh.

Finished Steel

The 1.10c. price for bars, plates and shapes disappeared March 1 according to program, leaving the market at 1.15c. for March and 1.20c. for second quarter, there being, of course, some exceptions when large lots for specific jobs were involved. The beginning of April, it is now hoped, will see a disappearance of the 1.15c. quotation. Sales of galvanized sheets at the mill price of 3.40c. have been extremely light. For one thing, many jobbers had contracts at much lower prices, made before the phenomenal advance in spelter, and became competitors of the mills, while for another thing consumers are quite averse to paying such high prices for galvanized sheets and if spelter does not decline sufficiently to permit galvanized sheets being sold at prices somewhat in harmony with those of the past the consumption will be materially reduced.

Current quotations are as follows for ordinary deliveries, quotations being f.o.b. Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.15c. to 1.20c.

Shapes, 1.15c. to 1.20c.

Steel bars and bands, 1.15c. to 1.20c., base; hoops, 1.25c. to 1.30c., base.

Refined iron bars, 1.15c., Pittsburgh; common iron bars, 1.12½c., Philadelphia; 1.12½c., Chicago.

Sheets, blue annealed, 10-gage, 1.30c.; black, 28-gage, 1.80c. to 1.90c.; galvanized, 28-gage, 3.40c.; painted corrugated, 28-gage, 2c.; galvanized corrugated, 28-gage, 3.45c.

Tin plate, $3.20 to $3.35 for 100-lb. cokes.

Steel pipe, 80 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 74 per cent off list.

Standard railroad spikes, 1.35c., Pittsburgh; 1.45c., Chicago.

Cold-rolled shafting, 70 per cent off list of March 15, 1915, f.o.b. Pittsburgh.

Structural rivets, 1.35c.; boiler rivets, 1.45c.

Chain, ⅜-in. proof coil, 3c.

Conditions in Mexico

The best impressions we can get regarding conditions in Mexico come from private correspondence that filters through on occasional mails. It is difficult, if not impossible, to draw general conclusions even from such sources, but they at least represent the daily happenings and are suggestive of the troublous times through which Mexico is passing. Commerce and industry must necessarily be at a standstill under the changing domination of conflicting parties, and mining is out of the question. The following excerpts from the correspondence of a managing engineer now at Guadalajara, Jalisco, covering a period of time from Jan. 10 to Feb. 25, show in a graphic manner the state of lawlessness that exists. They express the hope of the inhabitants in the "Villistas" and their fear of the "Carrancistas."

Jan. 10, 1915.

"We have had no violent experiences since the last attempt of the Villistas to enter the city at night, which was quickly repulsed. That was on the 30th of December, I think. For the last three days the Carrancistas have been getting ready to leave; some trains have left, but there are a great many of their troops still here. They have loaded enormous quantities of baggage and household furniture on the trains. We know nothing of the movements of opposing forces, but never lack for rumors of all kinds. This city is in a desperate state and the population in a state of dread all the time. Martial law in due form would be better than a disorganized state such as we have now.

"Some time back they ordered all rifles to be turned in. Foreigners were ordered to turn theirs in to their respective consulates. The authorities attempted to take possession of the arms in the consulates, and the Germans and French delivered theirs on a show of force. ———— sealed his consulate doors and went out of sight so as to avoid a discussion. The authorities attempted to force ———— to deliver up the British arms but he refused. They stood him up to shoot him and he dared them to go ahead. Then he sealed his doors and told them to break them down if they chose to do so. We admire his spirit, but if they go ahead and break his doors, they will also those of the American consulate. If bloodshed once starts over it, that will be the last of all of us, as they will then know that they have put their foot in it and might as well make a good job of it. They hung a railroad man last evening and shot another because the men did not wish to serve on the trains."

Jan. 31, 1915.

"Our latest has been an attempt by Julian to retrieve his lost fortunes and take this city from the Carrancistas. I guess he thinks that if Villa has to come over to take it again he will put some other *hombre* on the job as governor, seeing that Julian lost out after having been seated on the throne.

"Saturday, 30th, at 5.15 a. m., we heard one of the d—— shootings that we have yet been treated to—and it has to be something out of the ordinary these days if it is to attract attention. They came into town by every road available, and if they had had any head they would have had the place, as every cut-throat thought his time had come. Some yell, that, "Viva Villa," to judge by its effects. But somehow advantages were not utilized, and in the end Julian and his took up their quarters on the outside again. Some excitement, though, for disinterested people, these daylight attacks. Makes it bad about the cooking, as the *criadas* do not come to work for a day or two.

"About noon a cannon got working against the packing house where it was supposed some of the outsiders had taken refuge. Do not know what damage they did to the packing house, but they killed old ————, the moonshiner who lived at the defunct distillery near by. We know nothing of the outside world; mails, telegraphs and trains are dead."

Feb. 8, 1915.

"Today is another red letter day with all the excitement that goes with big doings. The Carrancistas are on the move again—another evacuation—and the grabbing of things belonging to other people makes us stay at home and keep the back gate shut securely.

"Last night troops were moving all night, and we knew that something was in the air. It is said that the Villistas have taken Colima.

"We have quite a time with the paper money. Diequez would not permit any Villa money to circulate, so that his own stuff should have the preference. This morning Villa paper is already being received in general. Everybody wears a glad smile this morning, even though they are fearful of what might happen before this crowd leaves. Exchange has been around eight and nine for one lately, but little business done of course. I do not believe I would buv up much for speculation if I had lots of idle money.

"Unless relief comes to this country soon there is going to be some actual human suffering for the needs of ordinary daily life. If one could believe that the experience of the people would do them some good in making them realize the responsibilities of life and country, there might be some consolation in the reflection; but reasoning powers they have not nor ever will have, so it becomes a matter of cruelty to animals."

Feb. 11, 1915.

"No change of scene; just the same old terror existing. Yesterday I saw part of a fracas in which one of these high-binders found a petty excuse for using his gun, and shot a man at the Casino below the American Club. We heard two shots, saw the victim run and fall at the corner, get up and stagger around while the high-binder looked for a chance to aim his pistol again. Our friend ———— stepped in between, as did also ————. Many others came running up, and they induced the victim to go to the palace where it was finally determined that he was not to blame. The governor was sorry, and the high-binder went away without being able to finish his story.

"Last night they shot two women on the street for being out after 8 p. m., and not being able to tell a good story quickly. Today they threatened some clerks because they declined to take some bad bills. I saw the soldiers go in after them. They said this afternoon that the clerks had been shot, but I could not confirm the story.

"This morning the brewery cashier declined to change a bad bill—said he had no change. Complaint was made and the soldiers went after him and made him open the safe, when it was found that he had lots of change. They fined the brewery a thousand *pesos*, and when payment was offered in their own money, they refused the bills as being bad money.

"Most of the high-binders have been living on their trains for the last several days, ready to move; but for some unknown reason they remain. How the people would like to see this bunch get out, and a set of real devils come in in their place, so that the city could have a little peace. I never thought that I could live in such an atmosphere as we have had here of late. What we go through every day would be the event of a life-time in the States. People are so thoroughly terrified that no one dares talk with anyone not an American or an Englishman. Our noble American Consul has been in hiding for three days; and today we see that a notice has been pasted on the door stating that affairs of our consulate have been turned over to the British Consul."

Feb. 13, 1915.

"Well, they put us on the map again today. Villa came in with a small bodyguard of cavalry, and the ovation he got from the city was something to be remembered. The American Consul came out of hiding this morning, and was around telling why he hid and left his *nationales* orphans. An old federal judge, Delgado, is said to be slated for governor. Poor Julian lost his job. Villa is supposed to have sent a lot of men after Dieguez, and will finish him now as he should have done in December. Our spirits have come up greatly since noon. Perhaps we shall be permitted to live a while longer."

Feb. 17, 1915.

"We have had several days of speculation as to what the new outfit would be able to do to the outs. Villa himself is at the front, and we imagine that they are doing some real fighting. Villa has an aeroplane with him. It left here yesterday morning and got part way to the front.

"We hear that Villa has declared the country cut in two parts, and that the line runs from below Manzanillo to below Tampico. That puts us in the north, for which we are thankful. All of us are now figuring on when we can do something. These folks are now busy cleaning up the town of traces of Carrancistas. I guess that they get away with a good many of them, and I hope they get the last of them and make good Indians of them.

"They say that Julian will have his job back after all, and I would rather he did, as we are better off if we have someone that we know personally. He has been expected in town for a day or so, but his feet must have been sore from the brush run that he made, and so he has been slow getting back. Dieguez took away everything in the way of an engine that could be moved, and those that could not be moved he tried to ruin. He broke up the railway shops and raised Cain generally so they cannot rustle engines for traffic. If Dieguez ever gets back here, it's good-bye Guadalajara."

Feb. 25, 1915.

"I have your letters of Nov. 11, Jan. 11 and 25, all having come in a few days ago by the first train bringing mail for some time. Having ventured out toward our diggings, I was gone a few days and so have not written immediately. I got within speaking distance of the mines, that is, speaking over the telephone forty miles. That is doing fairly well, though, considering the circumstances.

"The Southern Pacific track from Orendain to La Quemada consists of two streaks of rust and a mushroom bed; at least the rotten wood that was formerly ties can serve now only for planting mushrooms. They have not had a new tie in over a year, and whenever they rustle a car of ties, some military train comes along and takes them for fuel. They have a locomotive, two cars, a conductor and engineer at La Quemada, but none of them can be moved as there is no oil for the engine, and the crew is looking for something to eat.

"We really know nothing of what is going on in the country. There has been heavy fighting down toward Colima, but what the result is we know not, and people are fearful that the old crowd may return some day. Our only satisfaction, and it may be an illusion, is that living is extraordinarily cheap for those of us that are on gold salaries. The poor devils that are on a *peso* basis are in a bad way. The natives also are in a bad way, as prices are frightfully high, and but little work to be had.

"Trains go out toward Irapuato frequently, and some come in, so mail is moving somewhat; but any day we may be cut off. If you get no mail from me in a long time, you may take it for granted that there has been a change of play and a new film on. If the Carrancistas get back into this place, our cake will be all dough."

Atlantic City Meeting of the American Electrochemical Society

The annual meeting of the American Electrochemical Society will be held in Atlantic City from Thursday to Saturday, April 22 to 24, 1915. The headquarters will be at the Hotel Chalfonte.

Sessions for the reading and discussion of papers will be held on Thursday afternoon and Friday morning and afternoon. On Thursday evening Professor William S. Franklin of Lehigh University will lecture on models of electromagnetic phenomena. On Friday evening an informal smoker will be held.

On Saturday morning a train will be taken to Philadelphia and sessions will be held in the morning and afternoon at the Harrison Chemical Laboratories of the University of Pennsylvania. Between the sessions lunch will be taken at Houston Hall. In the afternoon session a lecture will be delivered by Provost Edgar F. Smith of the University of Pennsylvania.

New Orleans Meeting of the American Chemical Society

The fiftieth meeting of the American Chemical Society will be held at New Orleans, La., from Wednesday, March 31, to Saturday, April 3, 1915. Headquarters are at the Hotel Grunewald.

The feature of the convention will be a general meeting on April, in which nineteen different papers will be presented in the contributions of the chemist to different industries. The opening address will be made by Dr. A. D. Little, of Boston, on the industrial resources and opportunities of the South, while in the evening Dr. Bernhard C. Hesse will speak on the chemists' contribution to the industrial development of the United States.

The Electrochemical Production of Organic Compounds

The New York Section of the American Electrochemical Society held the fourth regular meeting of the season at the Chemists' Club on the evening of Feb. 5. This was a joint meeting with the New York sections of the American Chemical Society and the Society of Chemical Industry. The evening was devoted to a symposium of papers on the electrochemical production of organic compounds.

Introductory Remarks

Dr. COLIN G. FINK, chairman of the New York Section of the American Electrochemical Society, introduced the subject by the following remarks:

"The subject of organic electrochemistry is a new one in America. If you will look over the membership list of the American Electrochemical Society you will find that most of the members are metallurgists and inorganic chemists. Another large percentage is composed of electrical and mining engineers. The organic chemists form a very small group.

"The subject of organic electrochemistry is a very important one, yet owing to an unfortunate tendency on the part of the organic chemist to shun physical chemistry and a like tendency on the part of the electrochemist to shun things organic, the field of organic electrochemistry has been badly neglected. However, it was not the electrochemist who chose the inorganic lines but rather the inorganic chemists and engineers were induced to adopt electrochemical methods—methods which at first often seemed very impractical but eventually superseded all others. It was only a few years ago when the making of steel in the electric furnace was ridiculed by almost every chemist and engineer.

"There are three distinct reasons for introducing the subject of organic electrochemistry at this time:

"(1) In consequence of the European war the coal-tar industry in this country has received a great impetus.

"(2) Our European contemporaries, notably Elbs and his co-workers, have demonstrated conclusively that a large number of organic compounds, can be better and easier produced by electrochemical means than by any other.

"(3) Many of the electrochemical processes for inorganic products have been standardized and the electrochemist is looking for new fields to invade."

The Commercial Aspects of Organic Electrochemistry

Mr. F. AUSTIN LIDBURY, manager of the Oldbury Electrochemical Company of Niagara Falls and president of the American Electrochemical Society, presented a paper on the commercial aspects of electrochemistry.

Mr. Lidbury drew attention to the fact that the present disturbed conditions, which have thrown this country upon its own resources to a large extent, had made clear the brilliant position of the country in regard to its electrochemical industries; while quite another adjective would have to be applied in reference to the organic chemical industries. The reason for this was to be found largely in the fact that American Industrial genius ran along lines favorable to the development of the former, and unfavorable to the development of the latter.

It had been assumed by some that it would be an easy and natural matter for electrochemists to extend their triumphs in inorganic lines to organic lines; but with this view the speaker did not agree. With a relatively few exceptions, the obvious applications of electrochemical methods to organic industry (putting aside the use of electrochemical products such as chlorine, caustic, sodium, carbide, etc., in organic industry) were largely confined to the conversion of one intermediate product into another intermediate product; and as in such cases it would rarely happen that the electrochemist could feel on safe ground either as to his supply of the raw intermediate product, or as to the market for his finished intermediate product, the electrochemist was usually too much of a business man to enter a field of that kind. Consequently it must be left largely to the organic chemist, since it was under his purview that the commercial aspects of such change of products came.

The speaker compared, on the basis of reductions and oxidations equivalent to a gram molecular weight of hydrogen, energy costs involved in electrolytic methods with power taken at various figures, with the cost of chemical reducing and oxidizing materials. He showed that under most conditions a fair margin apparently existed, with the exception of the very cheapest reducing materials, such as iron, in favor of electrochemical methods. The difference was particularly marked in the case of oxidations, and the same remark would, of course, apply to substitutions.

However, two facts were to be set against this. In the first place, to do a unit of chemical work in unit time an electrolytic plant would usually be very much larger than a chemical plant; require very much more room; be very much more expensive; require more expert attention, and on account of the extreme severity of the demands of electrolytic methods on materials employed for plant, etc., the upkeep would also usually be higher.

In the second place, the working out of an electrolytic method requires a very much greater amount of time, thought intelligence and expenditure than the working out of a chemical method. Though this might not amount to much as regards laboratory investigation, anyone acquainted with the electrolytic industries would be aware of the greater difficulties which invariably had to be overcome in preparing such a process for large-scale operation, and in that important phase known as "establishing practice."

While American industries led the world in the application of intelligence to such industrial problems as were conducted on a sufficiently large scale, we had apparently not yet reached the stage where the same grade of intelligence was being applied to problems of smaller dimensions. This was one of the principal reasons for the difference in success between the inorganic electrochemical and the synthetic organic chemical industries in this country. It would be one of the things militating against a considerable adoption of electrochemical methods in the organic industries, as most of these applications would relate to problems individually of small commercial importance.

Lastly, Mr. Lidbury expressed considerable doubt as to whether organic chemists would be capable of themselves applying electrolytic methods to their own problems. An organic chemist was usually constitutionally unfitted to be any other kind of a chemist. It was, therefore, his recommendation that where there appeared to be a field for application of electrolytic methods, electrochemists should be employed for investigation purposes; and that they should be given not merely a specific problem to work out, but the run of the whole particular field involved, since electrochemistry was not so much a collection of methods as a habit of thought.

Electrolytic Preparation of Organic Compounds

The next paper was presented by Dr. HAROLD HIBBERT, of the Mellon Institute of Industrial Research on "the electrolytic preparation of organic compounds."

A review of the literature and patents published during the last twenty-five years brings out one fact very clearly, namely, that, as in so many other branches of

the chemical industry, the honor of being the pioneer in this development of the art belongs, one might say, almost exclusively to Germany. During the period under review (up to the end of 1910) some eighty-nine patents on this subject were granted in Germany, six in France, three in England and four in this country.

An analysis of the eighty-nine German patents shows that some fifty of these are concerned with the synthesis of dye-stuffs, or intermediate products concerned in the manufacture of dye-stuffs, as indicated in the following table:

Subject.	Total Number of Patents
Reduction of aromatic nitro compounds	39
(a) Reduction of nitro derivatives to give azo and hydrazo compounds	13
(b) Nitro derivatives to give amines (aniline, benzidine, m. phenylene, diamine, etc.)	6
(c) Nitro derivatives into nitroso compounds	1
(d) Nitro derivatives into amido phenols	12
(e) Reduction of azo and hydrazo derivatives to give amines (benzidine, etc.)	6
(f) Reduction of azo derivatives to give hydrazo compounds	1
	39

In addition to these patents there are between ten and fifteen concerned with the synthesis of various special products, as, for instance, the reduction of indigo, oxidation of alizarin and the direct formation of azo dye-stuffs.

The remaining patents have reference to various minor applications, such as the manufacture of iodoform, saccharin, vanillin, phthalic acid, etc. It will be noted that only in a very few instances has it been found possible to apply the electrochemical methods to the synthesis of aliphatic compounds.

In the author's opinion the wonderful progress associated with the caustic alkali-chlorine industry is to be connected principally with two factors: (1) The entire absence of a monopoly of the raw product. (2) The general demand in practically every branch of the chemical industry for these products.

Three factors are necessary for the development of any (synthetic organic) chemical industry: (1) Cheap fuel. (2) Cheap transportation. (3) Other factors, e.g.: (*a*) An ample supply of raw material obtainable at a sufficiently low cost; (*b*) satisfactory patent protection; (*c*) absence of inimical legislation.

In the writer's opinion there would seem to be no question but that a very considerable number of intermediate products required in the synthetic-dye industry could be manufactured in this country with satisfactory financial returns. It is of interest that the German patents on the principal processes have already lapsed. While most of the patents issued up to the present are concerned either with processes of oxidation or reduction, there would seem to be also a considerable field for the application of electrolytic processes to the synthesis of "substitution" products, that is, to the manufacture of chlorinated compounds of various descriptions, etc., but this will require an extended study of the technique suitable to the particular problem to be solved. However, in view of the great desire on the part of the electrochemists to find an outlet for the surplus chlorine produced in the manufacture of caustic alkali, it would seem probable that before long attention will be directed to this field as a possible outlet. Of the various processes, which have already been shown to be highly profitable commercially, coming to the writer's knowledge, those of iodoform and para-hydroxy-amino compounds would seem to form the most striking instances.

The best process for making iodoform would seem to be that developed by Foerster and Mewes.[1] A solution containing five parts of sodium carbonate, seventeen parts potassium iodide, ten parts 96 per cent alcohol and 100 parts water are electrolyzed, using smooth sheet platinum as anode and sheet lead as cathode. The temperature is maintained at 60-70 deg. C., with a current density of 1-2 amp per square decimeter. In order to avoid losses, due to reduction, the cathode is covered with parchment paper. Carbon dioxide is conducted into the solution at such a rate that this retains a distinctly yellow color. Iodoform settles at the bottom of the vessel in a perfectly pure state and, employing a current density of 1 amp per square decimeter, a yield of 95-97 per cent, calculated on the current used, is obtained. One kilowatt-hour gives about 500 grams of iodoform.

Apparently the simplest process for the preparation of amino phenols would seem to be that of F. Darmstaedter,[2] which consists in electrolyzing a suspension of nitro benzol in 50 per cent aqueous sulphuric acid. The two poles are separated by a diaphragm and it is necessary to agitate very vigorously. The cathode consists of carbon, the anode of platinum and a current density of 6 amp per square decimeter is employed. Using an excess of nitro benzol, it is stated that a yield of para-hydroxy-amino phenol up to 86 per cent can be obtained.

Another possible application of electrochemical methods would seem to lie in the utilization, for example, of waste dilute nitric acid for the manufacture of nitro compounds, as for instance the manufacture of nitro naphthalene according to Tryller's method,[3] which consists in agitating vigorously one part of molten naphthalene with fifty parts of dilute nitric acid at a temperature of around 82-85 per cent C. The electrolysis is carried out using a platinum cathode and aluminium anode. It is not necessary to use a diaphragm. The mononitro derivative, practically free from dinitro, is obtained in this way.

The Electrolysis of Aromatic Compounds

Dr. George Shannon Forbes, of Harvard University, presented a paper on "The Electrolysis of Aromatic Compounds," which was illustrated in a very interesting way by numerous experiments.

The typical reactions in the electrolysis of aromatic compounds are oxidation, substitution and reduction. Typical oxidations are those of aniline to aniline black, and indigo white to indigo (the first recorded experiment of this kind, Grotthus, 1807) which were demonstrated by Dr. Forbes by experiment. Important financially are such reactions as the oxidation of benzene to quinone, with subsequent reduction to hydroquinone, the oxidation of anthracene to anthroquinone, and that of o-toluene-sulphamide to saccharin.

In substitution an ion like Cl' or Br' may be discharged and act directly, or through migration of anions, like SO_4'', NO_3', or NO_2' the concentration of a molecular species may become so great on the surface of the anode as to cause reaction. This was illustrated by the preparation of Orange II.

Electrolytic reduction was illustrated by the preparation of azobenzene from nitrobenzene at a nickel cathode, and by the reduction of pyridine to piperidine at a lead cathode. The familiar scheme of reduction of nitrobenzene both in alkaline and in acid solution was discussed.

The great number of variables in electrolysis, such as electrode material, overvoltage, current density, catalysis by the electrode or by dissolved substance, the differing effects of temperature on primary and secondary reactions, added to the variables significant in ordinary organic work, make the situation very complicated, but in these very complications lies the possibility of preparing compounds from costly materials, with greater efficiency and profit than is possible by the ordinary methods of organic chemistry. It appears probable that

[2] D. R. P. 181,116 (1903).

[3] D. R. P. 100,417 (1897).

in cases like this, the difficulties and disadvantages of the electrochemical method will be outweighed, and that electrochemical methods will prove of the greatest value.

A general discussion of the subject followed in which Messrs. Bogart, Baskerville, Doremus, Richards, Hooker, MacDowal and others participated.

The Fixation of Atmospheric Nitrogen*

BY W. S. LANDIS

Chief Technologist, American Cyanamid Company

I assume more or less familiarity with the use of nitrogen in one or more of its various combinations, for even a partial catalog of the most common commercial nitrogen compounds would read like a few pages out of *Olsen's Chemical Annual* or the *Chemiker Kalender*. I will not even give statistics of consumption of the nitrogen compounds, because the very complex nature of these statistics would make them difficult of comprehension if merely read from prepared tables. I need but say that in tonnage alone the nitrogen compounds stand well at the head of the list of the world's trade in heavy chemicals, nitrate of soda and sulphate of ammonia being produced in 1913, to the value of $200,000,000.

Chilian Saltpeter and Coke-Oven Ammonia

Not including atmospheric nitrogen, whose utilization is yet in its infancy, we are practically dependent for our supply of this valuable element upon the nitrate deposits of Chile and upon its recovery as a by-product from our fuels. The Chilian deposits have been so frequently and fully described elsewhere that we can omit reference to the same here. The end of this source of supply is, however, in sight, and it will only be a few years until Chilian nitrate will pass into history along with our anthracite coal and the Saxon silver-lead ores.

The recovery of ammonia as a by-product from fuel is entirely different, for in the coke oven and the gas producer we will have an ever-increasing source of this element for many centuries to come, from which it is obtained in one of its most valuable forms of combination, ammonia. This source of supply is, however, somewhat unsatisfactory, inasmuch as it is wholly a by-product of the coal distillation industry, a ton of coal yielding only 5 to 6 lb. of ammonia, and by-products as a source of primary supply have many limitations. This is well illustrated by the present status in Germany, from which country I have lately returned. There is in that country just now a considerable shortage of nitrogenous fertilizer because the Government has confiscated all stores of nitrate for military purposes. (The fertilizer industry there consumes about 800,000 tons of nitrate per year.) The coke ovens which we should expect would normally come to the rescue in such a crisis are, however, largely closed. Ammonium sulphate production is, therefore, correspondingly decreased just at a time when agriculture needs it most, and its lack is felt acutely. Since my return I have learned that the use of coal has been prohibited in Germany in order to force the use of coke and thus increase the supply of ammonia and tar.

We came very near having the same conditions arising in this country, for were the farmer in position to take his normal fertilizer requirements there would be a great sulphate shortage, as our own industrial depression has closed down many of our coke ovens, and we would have no ready means of meeting even a normal demand for sulphate. We thus see the disadvantage of a by-product source of such an important element as nitrogen, and we understand why inventors have turned so actively to finding a substitute for the Chilian nitrate and the coke-oven ammonia.

Fixation of Atmospheric Nitrogen

Naturally the inexhaustible store of atmospheric nitrogen has presented itself most prominently in this search for a new source. Neglecting the many proposals which have merely wasted much paper and ink in describing impossible methods for the fixation of our atmospheric nitrogen, I am going to devote my attention solely to the successful and at the present time commercially developed efforts in this field.

We can classify these successful attempts into three groups:

1. Direct synthesis of nitrogen and hydrogen to ammonia.
2. Combustion of nitrogen and oxygen in the electric arc.
3. Combination of nitrogen with metals or carbides.

Synthetic Ammonia

The only commercial process to-day, belonging to group 1, is the so-called Haber process. Dr. Bernthsen (this journal, Vol. X, p. 637, 1912) described this process at the Eighth International Congress of Applied Chemistry, and exhibited a small working model of the apparatus. I am sorry that I can add but little to the technical information he there presented, but the owners of this process have maintained the greatest secrecy with respect to its commercial development, and but little is known regarding the details in the commercial world.

As you will recall, this process consists in passing a mixture of three volumes of hydrogen and one volume of nitrogen, at a pressure of upward of 150 atmospheres over a suitable catalyzer operating at a temperature of some 500-700 deg. C. A single passage of this mixture through the apparatus causes a transformation of 2 per cent to 6 per cent of the nitrogen to ammonia, which is recovered from the apparatus by condensation and the rest of the uncombined gases are again returned to the cycle.

Too much honor cannot be shown the courageous chemists who have succeeded in placing this process on a commercial working basis. The difficulties seemed almost insurmountable. The catalyzer, which has taken various forms and compounds, principally metals and carbides, poisons very readily, and, therefore, extreme care must be taken in the purification of the gases. Purity which the average chemist would classify as C. P. finds no place in this industry, as that would lack almost as much of meeting the requirements of the process as the use of crude chemicals in the analytical laboratory. It took years of work to find a suitable metallic container for the high-pressure gas mixture, because of the permeability of most ordinary materials. However, most of these difficulties have been overcome, and I have been reliably informed that the Badische plant at Oppau supplied its allotted quota of sulphate to the German Sulphate Sales Company last year, but I greatly doubt that they did it at a profit if it was made from synthetically produced ammonia, with sulphate prices as low as they were in the early part of 1914.

This process as ordinarily understood is not supposed to involve the use of any considerable quantity of electric power (which is not quite true), but does require a large amount of highly skilled labor, for the units are small and complicated. This particularly suits it to the Rhine location, but renders its value in the United States rather questionable. I personally cannot see a future

*A paper presented before the Washington Section of the American Chemical Society on March 17th, 1915, and before the Philadelphia Section of the American Chemical Society on March 18th, 1915.

for its operation under American conditions, particularly in view of the competition of the much cheaper cyanamid process which furnishes the same end product—ammonia.

At Oppau the Badische company must dispose of large quantities of waste sulphuric acid and have a by-product hydrogen, hence local conditions favor the Haber process above all others.

Direct Combination of the Nitrogen and Oxygen in the Air

The second group of processes embraces those oxidizing the nitrogen of the atmosphere in the electric arc. It is well known that when air is heated to temperatures of about 1800 deg. C., the nitrogen oxidizes to NO and remains, on rapid cooling, in that form. At that temperature, however, the reaction velocity is very low and commercial working requires that temperatures of above 3000 deg. C. be used, at which temperature the reaction velocity becomes quite considerable.

Three types of apparatus are in commercial use for performing this reaction:

1. The drum furnace with disk arc, of Birkeland and Eyde.
2. The long tube furnace with spiral arc, of Schönherr.
3. The narrow furnace with fan-shaped arc, of Pauling.

There are numerous other proposed types of apparatus which are claimed to be superior to the above, as reference to patent literature in particular will show, but the above listed three furnaces are the only ones in actual every-day operation.

The product obtained by passing air through the arc of any of these furnaces consists of a highly heated gas containing from 1 to 2 volume per cent of nitric oxide. On cooling down to temperatures of approximately 600 deg. C., this nitric oxide unites with free oxygen to form nitrogen peroxide, NO_2; on further cooling of this nitrogen peroxide to below 140 deg. C., it polymerizes to N_2O_4. When brought into contact with water and oxygen this reacts forming a mixture of equal molecular parts of nitric and nitrous acids. By subjecting the nitrous acid to further action of the peroxide this is also changed to nitric acid with the liberation of nitric oxide, which again passes through the cycle.

Thus by suitable cooling of the nitric oxide in the presence of air and water one ultimately attains a product which consists almost quantitatively of nitric acid, and actual operating results of the large furnace plants have shown a steady recovery of about 90 per cent of the nitrogen oxides in the form of nitric acid or nitrate salts, the remainder being received as nitrite or not absorbed.

In general the handling of the nitrose gases from the arc furnaces is now well standardized, and the design of a condensation plant is almost as well understood to-day as that of a sulphuric acid plant. After passing the various systems of cooling apparatus, consisting of steam boilers, evaporators, etc., the gases enter aluminium condensers where the temperature is reduced to approximately 100 deg. C. They then enter a preliminary oxidation chamber so proportioned that they remain in the same at least one and one-half minutes before leaving, where the preliminary oxidation to peroxide takes place. The gases next pass into a series of four or five stoneware or granite towers where they are washed with water by a counter current system, remaining in the tower system for from three to five minutes. Of the nitrogen oxidized 90 per cent is here condensed as nitric acid, the most concentrated acid being obtained in the first tower, and averaging from 30 to 35 per cent HNO_3. After passing these condensing towers the gases usually enter a final tower fed with caustic soda liquor, where a further 3 to 5 per cent of the oxidized nitrogen is recovered as sodium nitrite. The remaining 5 per cent passes out into the air unabsorbed.

As above mentioned, these towers deliver a 30 to 35 per cent nitric acid; this can be further concentrated to 50 per cent nitric acid, using the heat of the hot gases issuing from the arc furnace to perform the necessary evaporation. It is not possible to carry this evaporation much above 50 per cent for economical reasons, and where higher concentration of nitric acid is demanded special complicated concentration processes must be employed.

Dilute nitric acid, as obtained from the towers, finds little use in industrial processes, and it is difficult to transport. Most of the nitric acid plants, therefore, either concentrate it to 96 per cent acid by special means, or convert it into calcium nitrate for fertilizer use, or into ammonium nitrate for explosive purposes. In the latter case most of the ammonia used to-day in the nitric acid plants, operating on the arc system, is obtained from cyanamid.

It is quite probable that calcium nitrate will soon disappear from the fertilizer market as it certainly cannot be sold at a profit in competition with Chilian nitrate or ammonium sulphate even when the latter is made from cyanamid.

As we shall see later these arc processes require enormous quantities of cheap electric energy, and must be located near such power centers. We have no cheap power in the United States, and there is no immediate prospect of our having an arc process in continuous large-scale operation within our borders. Our Western powers are far from markets and transportation of the nitric acid as such to the East is almost out of the question.

Cyanamid Process

The third group of processes, as catalogued in my introduction, embraces fixing nitrogen by metals or carbides, and has reached its highest development in the cyanamid process, which last year produced throughout the world in the fourteen factories at present in operation, some 300,000 tons of material, carrying over 20 per cent nitrogen.

The inventors of the cyanamid process originally attempted the synthesis of cyanides by subjecting barium carbide to the action of nitrogen, which, as is well known, forms barium cyanide. On attempting to use the cheaper calcium carbide in place of barium carbide, Professors Frank and Caro found that instead of obtaining cyanide they obtained a new material, which proved to be calcium cyanamid. It was later found that this material could be utilized directly in agriculture, and from this discovery has grown the enormous cyanamid industry which has proven itself to be the cheapest method of fixing atmospheric nitrogen at present in existence.

Reference to the literature existing upon the manufacture of cyanamid seems to lead one to suppose that it is a comparatively simple matter to carry out the reaction so frequently written:

$$CaC_2 + N_2 = CaCN_2 + C.$$

This might be true to a limited extent were this the only reaction that we chemists at Niagara had to contend with, but I can merely say to you that even this reaction itself it so complicated that while it is well known that it is a reversible one, no one has yet succeeded in correctly establishing its equilibrium constants. A laboratory study of this reaction has been

carried out both in this country by Prof. M. de Kay Thompson (this journal, Vol. VIII, p. 617 and 687, 1910), and abroad by Professor Haber, but neither of them has succeeded in mastering the same, because of the peculiar difficulties that arise in a study of it.

Naturally if the highly skilled chemical laboratories have met with these difficulties, we can assume that practice runs against a few of them itself. But aside from the fundamental absorption reaction, as written above, there are a number of other complications that arise in this industry which we have to meet with in our every-day work, and which I shall call to your attention to show that the actual carrying out of the cyanamid process requires something more than writing the reaction on a piece of paper.

The fertilizer industry, into which most of our material at present goes, is a rather peculiar one, and probably has more peculiar fads and precedents than almost any other highly developed industry in the country. Naturally to sell to fertilizer men material we must take into account all of the peculiarities of the industry, and we must satisfy them—a fact which further complicates the cyanamid industry itself. But it may be assumed that inasmuch as cyanamid is being produced and sold at the rate previously mentioned we have succeeded somewhat in meeting these fancies.

The first stage of the cyanamid process involves the production of calcium carbide. To produce day after day a high-grade calcium carbide that meets the peculiar requirements of the cyanamid industry is quite an art in itself. There are no journeymen carbide workmen in our country, and we had to start out and develop our own furnaces and methods of operation. We had to seek sources of raw materials for this manufacture, which are quite different even from those which meet the requirements of the manufacture of lighting carbide, and we have to operate our furnaces in a certain peculiar way in order to combine these raw materials into a product of such structure and grade that we can make cyanamid out of it successfully. As may be recalled, Moissan in his early work found that he could not nitrify certain kinds of carbide, showing that there are conditions existing in our carbide manufacture that are different from those in the manufacture of lighting carbide.

Our next great problem was to grind this special grade of calcium carbide so that it passes a hundred-mesh screen. Naturally this must be done without slacking the carbide, as hydrated lime does not make good cyanamid. Now 100-mesh carbide dust is almost as explosive as low-grade dynamite when exposed to the atmosphere on a damp day, or thrown out on damp ground, so that it is quite some little problem of itself to grind this carbide to the required degree of fineness and have a mill left at the end of the day's run.

Next comes the production of nitrogen. It is a comparatively simple matter for the chemist to make a few cubic centimeters of high-grade nitrogen in his laboratory, but if one were to call upon him for 2,000,000 cu. ft. of a practically pure nitrogen per day, such as we make at Niagara, he would probably have to do considerable research to find out just how this enormous quantity of such high-grade material could be made. In the early days of the cyanamid process, when the Ni-

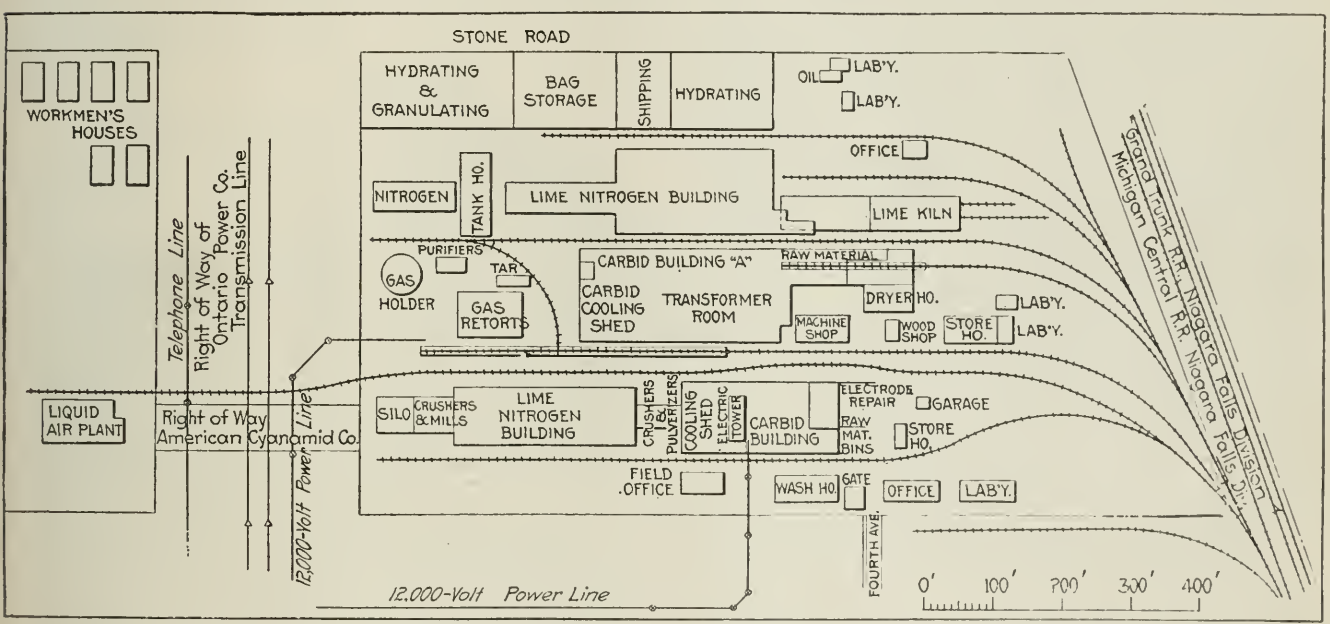

FIG. 2—PLAN OF AMERICAN CYANAMID COMPANY'S WORKS AT NIAGARA FALLS, ONTARIO

agara plant started, liquid air machinery was in a rather backward state of development, and we were forced to make our nitrogen by passing air over copper. The original plant was later enlarged. It was a long step from the combustion tube of the chemical laboratory to our present plant using retorts containing 5 tons of copper mass, but the problem has been successfully solved, and the new plant has been in operation with a minimum of trouble for some years.

In the early days of the industry at Niagara we could draw upon natural gas for reducing our copper oxide, so as to revivify it, but this gas supply has since failed and we were forced to put up our own coal gas plant. Even this coal gas plant is not a standard one, inasmuch as we are coking coal, not only for the production of gas, but also to furnish the coke for our carbide furnaces. We are running at temperatures in our retorts and obtaining qualities of coke and gas that the average city gas plant would not consider as possible of attainment, and it was only after considerable experiment that we ourselves demonstrated that our theories were correct in this respect and succeeded in finding gas engineers liberal-minded enough to incorporate our ideas into a working plant.

Eventually we had to install purification apparatus for taking out the impurities in the nitrogen, as it came from the copper retorts, and have equipped ourselves with soda towers for removal of carbon dioxide, refrigeration plants for drying, lime tanks for purification, etc., and have even developed this plant so highly that we have included a causticizing plant for recovery of our spent alkali.

After the development of the liquid air machinery, both in the way of capacity and reliability, the problem of producing pure nitrogen was much simplified, and our latest addition at Niagara includes what was probably the largest liquid air plant in the world at the time it was built, a year ago. This plant alone throws to waste almost 30 gal. of liquid air an hour, just to keep the apparatus flushed out and in good working order, not to speak of the thousands of cubic feet of rich oxygen-nitrogen mixture.

After one has overcome the difficulties in the production of a proper grade of nitrogen and of carbide, the next step is exposing these two to mutual reaction at a proper temperature, which is done in small individual ovens, holding from ½ to 2½ tons of carbide. The reaction itself is reversible, and particular precautions must be taken to always keep it running in the right direction until the carbide has all been nitrified. The physical and chemical conditions which must be met with in this part of our work are very complex.

The product removed from these ovens is a black, hard cake, which analyzes 22 per cent nitrogen and about 1 per cent un-nitrified carbide. This material, which we call "lime nitrogen," is next finely ground and stored in silos. The carbon set free in the reaction previously indicated is in the form of graphite, and it is not an easy proposition to find a satisfactory mill that will grind this material fine and at the same time not blow itself up from liberated acetylene derived from the presence of any uncombined carbide, or wear itself out grinding the lime nitrogen-graphite mixture. Extreme precautions are taken in this part of our operation, both in the mills themselves and in the elevating and conveying apparatus connected with them to avoid dangerous explosions, but I can truthfully say that in the years I have been connected with the company not a single injury has resulted from such explosions in our plant.

To prepare the lime nitrogen for agricultural purposes the finely ground material is partly hydrated to insure decomposition of the carbide it contains, and is then oiled to render it dustless, and stored in bulk, or packed immediately into sacks and shipped to the fertilizer mixer.

Calcium cyanamid tends to transform itself into a large number of organic compounds when subjected to the action of water, particularly at temperatures above normal, and, therefore, this hydration has proven an extremely complex problem, because we desire to avoid any such transformation, as agricultural experiments have shown that the calcium cyanamid in its unaltered form yields the best crop results.

Ammonia from Cyanamid

But agricultural uses are not the only purposes to which the cyanamid can be applied, as it is a very simple matter to convert the cyanamid into ammonia by the exothermic reaction

$$CaCN_2 + 3H_2O = 2NH_3 + CaCO_3.$$

If lime nitrogen is mixed in a slurry with water and subjected to the action of heat and high pressure, it is converted quantitatively into ammonia. In this country this use of cyanamid was not developed on a large scale outside our experimental laboratory until the beginning of this year, but while I was in Germany I saw in the yards of a big manufacturing concern there some sixty autoclaves, each capable of converting 10 tons of cyanamid into ammonia per day. This equipment was waiting railroad cars to move it out, and was in no sense experimental, because three similar plants have been in operation in Germany for at least three years. The cost of this transformation is hardly appreciable, and the purity of the product is quite high, requiring merely passing through a self-acting rectifying column for the removal of steam.

A New Ammonia-Phosphate Fertilizer

The ammonia so produced abroad is at present converted into a high-grade sulphate and a pure nitrate, and we are at work now in this country on producing a new fertilizer material, "ammophos," consisting largely of ammonium phosphate; my experimental laboratory at present working day and night trying to meet initial demands for this new material. Agricultural results the past season have been so phenomenal that our friends will not await the completion of a large plant for meeting the requirements, but have insisted on our converting our laboratories into a miniature factory.

Our product contains over 13 per cent NH_3 and 45-50 per cent P_2O_5, or over 60 per cent plant food, the bulk of the remainder being chemically combined water, and when mixed with the high-grade potash salts available will make a complete fertilizer some six times as concentrated as the average grades sold to-day.

Urea, Dicyandiamid, and Creatin from Cyanamid

It is also possible to transform cyanamid into urea, and I have made in my experimental laboratory a great deal of pure salt in a comparatively easy and simple manner.

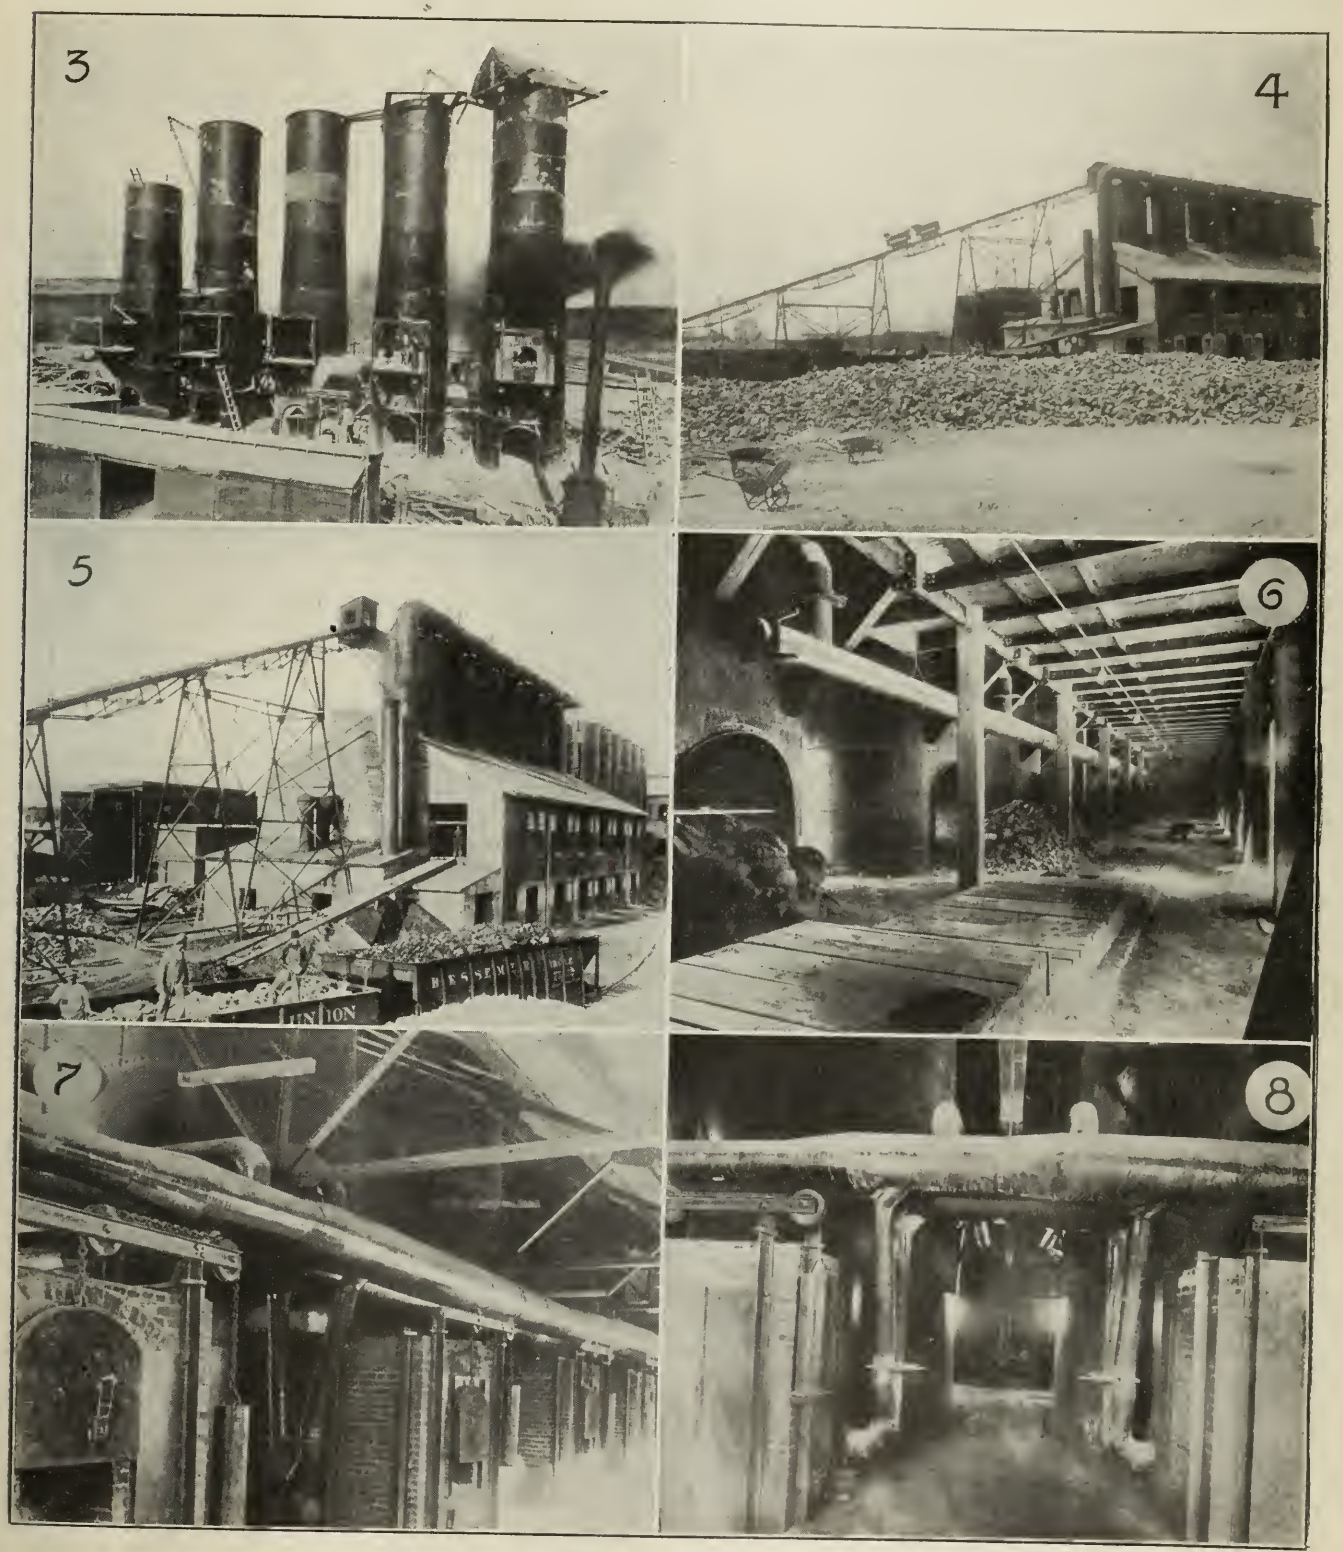
Similarly it can be converted into dicyandiamid by simple treatment with hot water. This material has been proposed for use as a deterrent in explosives, but which I think offers a much better field for transformation into the guanidines.

Such transformations of cyanamid abroad have received a great deal of attention, and there are numerous derivatives on the market. Just a few months ago I saw a sample of creatin which had been made in a chemical laboratory from cyanamid, and we feel that we in the industry are not very far from the synthetic production of foods when we can reach such a point in our chemical synthesis.

Cyanide from Cyanamid

When a special grade of cyanamid is melted down with a flux, such as common salt, it combines the free carbon present with the cyanamid radicle, forming cyanide. The resulting product of this fusion contains about 25 per cent of its weight in equivalent potassium cyanide; this crude form of cyanide dissolves very readily in water and filters rapidly from the insoluble, after which the solution is ready for metal extraction, or other uses to which cyanide in its dissolved form can be put.

Large scale experiments have been tried out in a number of the big cyanide plants scattered at various places throughout the world, and in every respect this material has shown an exactly equivalent value to the higher grade cyanides. The transformation of the cyanamid nitrogen into cyanide nitrogen is almost quantitative, and the fusion experiments can be carried out



FIGS. 3 TO 8—LIME PLANT OF AMERICAN CYANAMID COMPANY

without difficulty and at a low cost. We have here, therefore, a crude form of cyanide which can be prepared very cheaply and which could be readily delivered to the consumer at a price approximately one-third under the present prices of the higher-grade cyanide.

Abroad this material has been made in large quantities and transformed into the pure cyanide running approximately 127 per cent potassium cyanide equivalent, but we believe that with proper propaganda work our own cyanide users would find the low-grade material quite acceptable, provided it could be delivered to them at a cost sufficiently low to enable them to perform the extra dissolving and filtering operation which it involves over the use of the present high-grade alkali cyanides.

Cyanamid for Case Hardening

Cyanamid itself forms an excellent case-hardening material, and we have prepared a number of mixtures which are in steady use at our plant for performing this operation upon various machine parts which we are using. It works extremely rapidly at very low temperatures, but we have not yet succeeded in overcoming certain fads in large scale use of this material, and it has not met with any general introduction. We found the case-hardener is more concerned with the color of his hardening powders than he is with the actual work they perform, and as the colors and odors of our cyanamid products are rather fast we have not found it interesting to us to meet some of these peculiarities of the case-hardening trade. While abroad I saw these case-hardening materials being prepared by the hundreds of tons for use in the manufacture of armament and war materials, and the small factory engaged in their production has been swamped with orders ever since its inception.

Comparison Between Different Processes for Fixation of Atmospheric Nitrogen

The arc processes have shown themselves capable of producing nitric acid or nitrates; cyanamid itself is an entirely different product, but it is quite easy to produce ammonia from it, and there has recently been evolved abroad a most successful method* of oxidizing this ammonia to nitric acid, so that in case of competition with the Birkeland-Eyde process we are not entirely limited to the fixation of nitrogen, but can furnish this nitrogen in exactly the same form that the arc processes can, and at considerably less cost.

The raw materials for cyanamid are cheap—coke, limestone, air. We use only one-fifth the electrical power that the arc processes do per unit of nitrogen fixed in the form of cyanamid, respectively ammonia, and by the addition of a very small percentage more power we can convert our cyanamid into nitric acid. We require about the same quantity of labor to fix a unit of nitrogen in cyanamid as the arc process does in nitric acid, but since there is only a small fraction more labor used to transform cyanamid nitrogen into nitric acid we do not feel this is a great handicap when one considers our smaller power consumption. On the American continent, where water power is so expensive and so scarce, this difference readily offsets the additional labor necessary to make nitric acid from cyanamid.

Further, our cyanamid is easily transported and can be changed to ammonia or nitric acid at the end of its journey at the expenditure of a very small amount of steam and labor, so that we have the additional advantage in transportability of stable raw material, and subsequent conversion at the point of direct use. These commercial transformation units are small, and can be set up to supply even small amounts of ammonia or acid in a quite cheap and efficient plant. Practically all sulphuric acid plants in Germany have installed them since nitrate has disappeared from the trade.

There is no comparison between the initial investment required for a cyanamid plant and for an arc plant if one will include power development. The cyanamid plant, per unit of nitrogen fixed, requires an investment of only about one-quarter that required by the arc process, and for a cyanamid-ammonia plant about one-half that required by the Haber process. Even the combination of the cyanamid-ammonia-nitric acid process requires an investment of only one-third to one-half that for the arc process. In each case we are assuming exactly the same quantity of fixed nitrogen in the forms above designated.

Where electrical power is expensive, as in the United States, there is no question regarding the superiority of the cyanamid process for the fixing of atmospheric nitrogen, particularly for fertilizer purposes, and we eventually hope that the future development of our nitric acid process will enable us to compete in every line of nitrogen compounds with all other competitive sources.

The Niagara Falls Plant of the American Cyanamid Co.

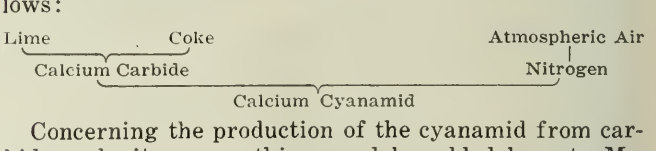
Mr. Landis illustrated his paper by a series of very interesting moving pictures, showing the most important steps in cyanamid manufacture at Niagara Falls.

As a substitute for the movies we give some representative views. As the Niagara Falls plant of the American Cyanamid Company comprises a 12-kiln lime plant, 25,000 horsepower of calcium carbide furnaces, a liquid-air plant which was the largest in the world a year ago, a gas plant of sufficient size to serve an average town of 25,000 inhabitants, a nitrogen retort plant, an ammonia refrigeration plant, a causticizing plant, a nitrification plant, a hydration plant, and innumerable crushers, mills, silos and feeding machinery, we cannot do more than give illustrations of some departments, chiefly the gas plant and the lime plant.

Fig. 1 gives a view of the works of the American Cyanamid Co. at Niagara Falls, Ontario, showing the lime plant at the extreme right, the coal gas plant at the extreme left, and the carbide and cyanamid plant in the center. A diagrammatical plan of the arrangement of the whole works is given in Fig. 2, which is reproduced from *Engineering News* of January 7, 1915.

The plant was started in 1909 with an annual output of 12,000 tons of cyanamid. The plant was enlarged in 1913 to an annual output of 32,000 tons, and in 1914 again enlarged so that the output is now 64,000 tons.

The whole operation may be concisely sketched as follows:



Concerning the production of the cyanamid from carbide and nitrogen nothing need be added here to Mr. Landis' paper.

The manufacture of calcium carbide is carried out in continuous operation in eight 20-ton, 3000-hp three-phase electric furnaces, each with three large carbon electrodes at the top. The charging platform for the furnaces is on a level with the top of the furnaces. The transformers are placed below the charging platform close to the furnaces, so as to require only very short connections between furnace and transformer.

*See, for instance, this journal, vol. 11, page 438 and 476, 1913.

Lime Plant.

The lime is burnt in the lime plant which was designed by the Improved Equipment Company of New York City, to whom we are indebted for the photographs reproduced in Figs. 2 to 8. The lime plant consists of twelve Doherty-Eldred lime kilns, equipped with the Eldred process and operated with induced draught. The first installation comprised six kilns, and six more were erected last year.

Fig. 3 shows the kilns in course of construction; the kiln shells have been erected and the fire-clay lining has been started. Fig. 4 is a view of the finished lime plant and shows the piping for induced draught and Eldred process. Fig. 5 is a view of the old lime plant with the new addition in course of erection, and shows the limestone being brought to the plant in cars. Fig. 6 is a picture of the lime discharge floor, Fig. 7 a picture of the furnace or firing floor with the piping for

the Eldred process and counterweight arrangement of the charging door, while Fig. 8 shows the arrangement of the return CO_2 and hot-air pipes and the damper control for the Eldred process.

The Eldred process and its applications to lime kilns was described very fully in an article by Mr. Carleton Ellis in our Vol. II, p. 495 (1904). The exhaust gas from the kilns is drawn by an exhauster from the top of the stacks and part of it is used as a "diluent" for the air in the fire boxes to get correct conditions of combustion. The balance of the exhaust gas is led to the waste stack.

The coke for the carbide manufacture is partly bought as such and the balance comes from the gas plant to be described later.

Nitrogen from Air.

As explained in Mr. Landis' paper the nitrogen (needed for the reaction with carbide to form cyanamid) must first be separated from the oxygen in the atmospheric air. Two different processes are being used for this purpose at Niagara.

The newer method, installed for the latest extension of the plant last year, uses liquid air produced by the Claude process. The oxygen is separated from the nitrogen by fractional distillation of the liquid air.

The older method used is the so-called copper sponge method, in which retorts filled with copper sponge are employed. When a series of these retorts is heated and air is blown through the copper sponge, the oxygen of the air combines with the copper, forming cupric oxide and leaving the nitrogen free. The flow of air is then diverted to a second series of heated retorts, also containing copper sponge, while coal gas is passed through the first series of retorts so as to reduce the cupric oxide to copper sponge. This is then used again for combining with the oxygen in a fresh amount of air and setting the nitrogen free, and so on. The process is therefore cyclic.

Coal Gas Plant

From the foregoing description it will be seen that the coal gas plant serves a double purpose. It provides coke for the carbide manufacture, and it provides the coal gas for the reduction of cupric oxide in the separation of nitrogen gas from atmospheric air.

The coal-gas plant has a capacity of 500,000 cubic feet per 24 hours. As Mr. Landis explains in his paper above, the standard coal gas process is not used; the retort benches are run very hot to produce a gas rich in hydrogen and coke low in volatile matter. They "are running at temperatures in the retorts and obtaining qualities of coke and gas that the average city gas plant would not consider as possible of attainment, and it is only after considerable experiment that we ourselves demonstrated that our theories were correct in this respect and succeeded in finding gas engineers liberal-minded enough to incorporate our ideas into a working plant."

The coal gas plant was installed by the Improved Equipment Company of New York City, to whom we are again obliged for the photographs from which the accompanying illustrations were made. There are seven benches equipped with the Doherty bench fuel economizer and sectional silica retorts and settings.

Fig. 9 shows the charging floor of the retort house with conveyor system and coal buggy, while Fig. 10 illustrates the manner of laying up the sectional silica retorts and settings. Fig. 11 is a view of the machinery room with Doherty washer cooler and centrifugal pump. Fig. 12 shows the rotary meter, Fig. 13 is a side view of the cooling coils of the Doherty washer cooler, and Fig. 14 an end view of the concrete purifying boxes showing covers.

Fig. 15 shows the ammonia still, Fig. 16 the gas holder of 100,000 cubic feet capacity, and Fig. 17 the Doherty washer cooler.

Before concluding this article, attention should be called to an admirable paper by Mr. Frank S. Washburn, president of the American Cyanamid Company, which was presented last month at a joint meeting of the American Institute of Electrical Engineers and the New York section of the American Electrochemical Society, and will come up for discussion again at the annual convention of the American Electrochemical Society at Atlantic City in April. It will be published in full in our next issue. An abstract of this paper, together with an account of another excellent paper, by Mr. Summers, on the general situation in the fixation of atmospheric nitrogen, will be found on page 241 of the present issue.

The first authentic discovery of tin in Nevada has been announced by the Mackay School of Mines. Samples from Battle Mountain proved to be stream tin of good quality.

The Formation and Decomposition of Sulphates During Roasting

BY BOYD DUDLEY, JR.

It is the purpose of the writer to present in this paper a general discussion of some of the chemical principles or laws that govern the formation and the decomposition of metal sulphates in the roasting furnace.

When a metal sulphide is heated in the presence of air to its kindling or ignition temperature, which varies with different sulphides and depends to some extent upon the grain size of the material,[1] there are formed primarily the metal oxide and sulphur dioxide,

$$MS + 1\frac{1}{2}O_2 = MO + SO_2$$

The sulphur dioxide thus formed may be carried as such from the furnace by the excess air, or it may be oxidized to sulphur trioxide,

$$2SO_2 + O_2 = 2SO_3,$$

the oxygen required for this process being derived from the atmosphere of the furnace or possibly from certain metal oxides that are capable of being reduced to lower states of oxidation.

Most metal oxides will, under proper conditions, unite with sulphur trioxide to form the metal sulphate,

$$MO + SO_3 = MSO_4.$$

In some cases the normal sulphate does not represent the only possibility since basic sulphates may be produced,

$$aMO + bSO_3 = aMO.bSO_3.$$

Wherein a and b are small whole numbers, the ratio of a to b being greater than in the case of the normal sulphate. Basic sulphates may, of course, be converted into the normal compounds and the reverse, under proper conditions.

The formation of sulphates according to this series of reactions is of frequent occurrence in the roasting of sulphide ores. Sometimes it is desired to maintain conditions in the furnace that will produce the greatest possible amount of some particular sulphate, for example in the sulphatizing roast of copper ore preparatory to leaching. But when the object of the roast is to eliminate sulphur as completely as possible, the formation of sulphates is undesirable, because in order to secure the desired result they must be subsequently decomposed. From the foregoing it would appear that the subject of sulphate formation and decomposition is one of considerable metallurgical interest, and that an analysis of the laws and principles and facts involved may prove of value.

I. Chemical Equilibrium Conditions

Consider first the general equation that has been used to represent the formation of sulphates,

$$MO + SO_3 \rightleftarrows MSO_4.$$

Such reactions are in general reversible as the equation indicates. Consequently it is possible to dissociate a sulphate into metal oxide and sulphur trioxide as well as to form it from these constituents, the direction in which the reaction proceeds being determined by the conditions imposed. Likewise the formation of basic sulphates from metal oxides and sulphur trioxide and their formation by the dissociation of normal sulphates are reversible reactions.

In addition to the simple dissociation of sulphates it is sometimes possible to effect decomposition by heating to sufficiently high temperatures with silica, ferric oxide, and other substances, forming thereby silicates, ferrites, etc. An example of the practical application of this is the decomposition of lead sulphate by silica in slag roasting. Such reactions as the latter, however, are practically irreversible under roasting conditions and, therefore, do not possess so great a theoretical interest as do the others that have been mentioned.

Viewed from the standpoint of the phase rule the system composed of a metal sulphate, the oxide, and sulphur trioxide is monovariant, i. e., at a given temperature a definite concentration of sulphur trioxide must be maintained in the gas phase in contact with a metal sulphate and oxide in order to maintain equilibrium. In other words the dissociation tension of a sulphate with respect to sulphur trioxide is constant at constant temperature.

It is not possible with the aid of the phase rule to calculate the values of the equilibrium concentrations or dissociation pressures that correspond to various temperatures; they must be determined experimentally in the case of each compound. However, experiment has shown that the dissociation of a sulphate, whether into oxide or only into a basic sulphate, to be an endothermic reaction. From this fact it is possible to state, with the aid of the principle of Le Chatelier,[2] that the dissociation tension of a sulphate increases with increasing temperature. It can also be shown that the basic sulphate resulting from the dissociation of a normal sulphate possesses at given temperatures lower dissociation tensions than does the compound from which it is formed. There is, of course, one temperature, that of the co-existence of the two sulphates and the oxide, at which the dissociation tensions of the two are equal.

It follows from the above that, if a metal sulphate is held at constant temperature in a space wherein the sulphur trioxide concentration is less than the equilibrium concentration corresponding to the prevailing temperature, the sulphate will undergo dissociation. If the sulphur trioxide concentration is kept constant, the dissociation will continue either until the sulphate is completely converted into oxide or is converted into a basic compound, the dissociation tension of which is less than the prevailing partial pressure of sulphur trioxide.

In case the formation of a basic sulphate is possible and the normal sulphate is held at constant temperature in a space containing a lower sulphur trioxide concentration than corresponds to the dissociation tension of the basic sulphate, the normal compound will first dissociate until it has been converted into the basic sulphate, which in turn will dissociate with the production of perhaps a second basic compound, or more commonly the metal oxide. On the other hand, if a metal oxide is held at constant temperature in a space wherein is maintained a higher concentration of sulphur trioxide than corresponds to the dissociation tension of the sulphate at the prevailing temperature, the oxide will be sulphatized, the normal sulphate being produced directly from the oxide only when basic sulphates do not exist. When basic sulphates are possible, the process of forming the normal compound will be the reverse of the process of its decomposition, as described above.

The view may be maintained that such considerations as have been outlined above are of no practical value in a study of the reactions of roasting, because in the roasting furnace the gases are drawn off continuously and with such rapidity that the sulphur trioxide concentration is maintained at an extremely low figure. Numerous analyses of roasting furnace gases appear to support this contention. The fact remains, however, that sulphates are formed during the roasting of sulphide ores, and that in many cases they are subsequently decomposed. In view of this, what are the reactions and what considerations do apply, if the foregoing do not?

The fallacy of such arguments doubtless lies in the

[1] Hofman, General Metallurgy, p. 403, 1913. Friedrich, Metallurgie, VI, 170, 1909.

[2] Nernst, Theoretical Chemistry, Translation 6th Ger. Ed., p. 676.

assumption that the concentration of sulphur trioxide in the furnace gas as a whole is the same as that in the gas immediately in contact with the roasting ore. Such is not the case. The concentrations of sulphur oxides in the gas in contact with even the topmost layer of grains in a roasting bed of ore are probably higher than in the furnace gas as a whole, owing to absorption and to the rate of diffusion of these compounds through the film of gas in contact with the solids. Laying aside this point for the present, it cannot be denied that the gas in the interstices of the ore bed is usually much richer in sulphur oxides and poorer in oxygen than is the furnace gas or the flue gas. Otherwise rabbling or stirring the roasting ore would serve no useful purpose, while in fact rabbling does accelerate the process of roasting by exposing new particles of ore to the direct action of the furnace gas, by liberating the sulphur oxides from the interstices of the ore bed, and by thus increasing the oxygen concentration within these spaces.

Inasmuch as it is the sulphur trioxide concentration in the gas in close contact with the roasting ore and not its concentration at some distance away that constitutes a determining factor in the formation and dissociation of metal sulphates, it becomes evident that, in the consideration of these reactions, attention must be directed toward the composition of the intersticial gas and toward the reactions occurring in such spaces rather than toward the composition of the furnace gas as a whole. But it must be remembered that thoroughness and rapidity of stirring or rabbling together with the depth of the bed of ore being worked constitute important factors in determining the average differences in composition that may exist between the intersticial gas and the furnace gas.

The formation and decomposition of a metal sulphate according to the reversible processes described in a preceding paragraph is in many respects similar to the formation and dissociation of calcium carbonate, according to the reaction,

$$CaCO_3 = CaO + CO_2.$$

In the case of the sulphate the process is not quite so simple and does not lend itself so readily to investigation, because of the complication arising from the dissociation of the sulphur trioxide according to the reaction,

$$2SO_3 \rightleftarrows 2SO_2 + O_2.$$

The reaction is reversible as is shown by the equation. It is endothermic when proceeding from left to right, which indicates that increasing temperature produces a change in the equilibrium that causes, under given conditions, a more complete dissociation of the sulphur trioxide.

Since at the elevated temperatures of the roasting furnace the reactions of sulphate formation and decomposition occur in company with the reversible reaction between the sulphur oxides and oxygen, the two processes are inseparably linked, and the former cannot be well understood without a clear understanding of the latter. Therefore a discussion of the sulphur trioxide, sulphur dioxide, and oxygen equilibrium will be presented.

The most useful information in regard to this reaction is obtained from the law of chemical mass action, which states that at a definite temperature equilibrium among the three gases is defined by the equation,

$$\frac{C^2_{SO_2} C_{O_2}}{C^2_{SO_3}} = K.$$

Wherein C_{SO_2}, C_{O_2} and C_{SO_3} are the concentrations of the gases designated by the subscripts, and K is the reaction constant. The value of K, while constant for each temperature, increases with increasing temperature. This, it will be noted, indicates under given conditions a decrease in the concentration of sulphur trioxide in the equilibrium mixture as the temperature increases.

The determination of the values of the equilibrium constant of this reaction has been the object of a number of investigations,[3] and, while the results of the various observers are somewhat conflicting, it appears that those of Bodenstein and Pohl are perhaps the most reliable. Accordingly their figures will be quoted, and used in certain calculations that are to follow. Table I contains the values of K determined by these investigators.

Table I—Equilibrium Constants of SO_3, SO_2, and O_2, Reaction at Various Temperatures

Temp. C.	K	Log K
528°	1.55×10^{-5}	−4.810
579	7.55×10^{-5}	−4.126
627	3.16×10^{-4}	−3.500
680	1.12×10^{-3}	−2.914
727	3.54×10^{-3}	−2.451
789	1.26×10^{-2}	−1.900
832	2.80×10^{-2}	−1.552
879	8.16×10^{-2}	−1.089

The values of K given in the above table apply to the reaction,

$$2SO_3 \rightleftarrows 2SO_2 + O_2.$$

and, in order to use these values in calculations, it is necessary to use the concentrations of the gases expressed in gram molecules per liter. It happens that calculations of the kind that are to be made are more conveniently performed and the results are more readily interpreted, when the partial pressures of the gases are used in place of the concentrations. Also it will be more convenient to write the equation in the form,

$$SO_2 + \tfrac{1}{2}O_2 \rightleftarrows SO_3.$$

The conventional mass action equation for the reaction, when so expressed and when the partial pressures of the gases are being considered, is

$$\frac{p_{SO_3}}{p_{SO_2}\sqrt{p_{O_2}}} = K_1.$$

Wherein K_1 is the mass action constant, the subscript being employed to distinguish it from the K used above.

Calculation of the values of K_1 from those of K is accomplished with the aid of the gas law equation,

$$pv = NRT.$$

Wherein p is the pressure of the gas under consideration; v is its volume; N is the number of gram molecules or mols involved; R is the gas constant; and T is the absolute temperature.

Now the concentration, C, of any gas expressed in mols per liter is N/v, N being the number of mols involved and v being the volume of the gas in liters under the assumed conditions.

Hence the gas-law equation may be expressed in the form,

$$p = CRT, \text{ or } C = \frac{p}{RT}.$$

Substituting for the concentrations, C_{SO_2}, C_{O_2} and C_{SO_3}, in the first mass-law equation their equivalents, p_{SO_2}/RT, etc., there is obtained the equation,

$$\frac{p^2_{SO_2} p_{O_2}}{p^2_{SO_3}} \cdot \frac{1}{RT} = K, \text{ or } \frac{p^2_{SO_2} p_{O_2}}{p^2_{SO_3}} = RTK.$$

Extracting the square root of the last expression and inverting both sides gives

$$\frac{p_{SO_3}}{p_{SO_2} p^{\frac{1}{2}}_{O_2}} = \frac{1}{(RTK)^{\frac{1}{2}}}.$$

[3] Knietsch, *Berichte d. Deut. Chem. Ges.*, XXIV, 4069, 1901. Mineral Industry, X, 622, 1901. Bodländer and Koppen, *Zeit. für Elektrochem.*, IX, 787, 1903. Bodenstein and Pohl, *Zeit. für Elektrochem.*, XI, 373, 1905. Von Lucas, *Zeit. für Elektrochem.*, XI, 457, 1905.

Combining this with the second mass-law equation involving K_1 yields the relation,

$$K_1 = \frac{1}{(RTK)^{\frac{1}{2}}}.$$

The value of R to be used depends upon the unit in which it is desired to express the gas pressures. If these are to be expressed in millimeters of mercury, $R = 62.4$, and the expression relating K and K_1 becomes

$$K = \frac{1}{(62.4\ TK)^{\frac{1}{2}}}.$$

The temperature, T, is expressed in degrees, C, on the absolute scale.

With the aid of the above equation, Table II, containing values of K_1 and log K_1, has been prepared. Plotting

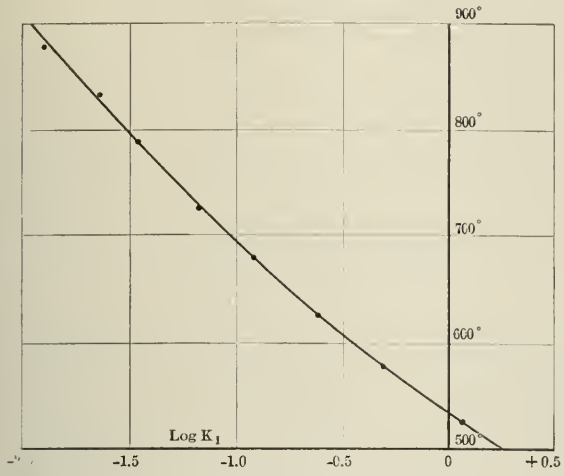

FIG. 1—VARIATION OF LOG K_1 WITH TEMPERATURE

these values of log K_1 against their corresponding temperatures gives Fig. 1. From this the values of log K_1 and K_1 at intervals of 50 deg., beginning at 500 deg., are taken to form Table III.

TABLE II—VALUES OF K_1 AND LOG K_1 AT VARIOUS TEMPERATURES

Temp. C.	K_1	log K_1
528°	1.14	0.057
579	4.96×10^{-1}	−0.304
627	2.39×10^{-1}	−0.622

727	6.70×10^{-2}	−1.174
789	3.46×10^{-2}	−1.461
832	2.27×10^{-2}	−1.644
879	1.29×10^{-2}	−1.890

TABLE III—VALUES OF K_1 AND log K_1 AT 50° INTERVALS BEGINNING WITH 500°

Temp. C.	K_1	log K_1
500°	1.78	0.250
550	7.95×10^{-1}	−0.100
600	3.55×10^{-1}	−0.450
650	1.78×10^{-1}	−0.750
700	9.23×10^{-2}	−1.035
750	5.13×10^{-2}	−1.290
800	3.06×10^{-2}	−1.515
850	1.82×10^{-2}	−1.740
900	1.10×10^{-2}	−1.960

By substituting the proper value of K_1 in the mass-law equation and by using this in connection with the chemical equation, it is possible to calculate with reasonable certainty the composition of the equilibrium mixture that will result from bringing together specified amounts of sulphur trioxide, sulphur dioxide, and oxygen at a definite temperature and pressure.

A special case that, as will be subsequently shown, is of particular interest in connection with the formation and decomposition of sulphates, is when sulphur trioxide alone is decomposed, or when sulphur trioxide is formed by bringing together sulphur dioxide and oxygen in the proportions of two mols of the former to one of the latter. Starting with pure sulphur trioxide it is seen from the chemical equation that at equilibrium as many mols of sulphur dioxide have been formed as of sulphur trioxide decomposed, and half as many mols of oxygen have been produced as of sulphur dioxide. Consequently, in the equilibrium mixture the conditions are represented by the following equations:

$$\frac{p_{SO_3}}{p_{SO_2}p^{\frac{1}{2}}_{O_2}} = K_1$$

$$p_{SO_2} = 2p_{O_2}$$

$$p_{SO_3} + p_{SO_2} + p_{O_2} = p_t.$$

Wherein p_{SO_3}, p_{SO_2} and p_{O_2} are the partial pressures of sulphur trioxide, sulphur dioxide and oxygen, respectively; and p_t is the total pressure of these three gases. Eliminating p_{SO_2} and p_{O_2} from these equations yields a relation involving the partial pressure of sulphur trioxide in terms of K_1 and the total pressure, p_t.

$$\frac{p_{SO_3}}{(p_t - p_{SO_3})^{3/2}} = 0.385\ K_1.$$

This equation is useful in calculating the partial pressure of sulphur trioxide in the equilibrium mixture resulting from the dissociation of this compound under given conditions of temperature and total pressure. The solution of the equation for p_{SO_3} is most readily accomplished by trial.

The composition of equilibrium mixtures resulting

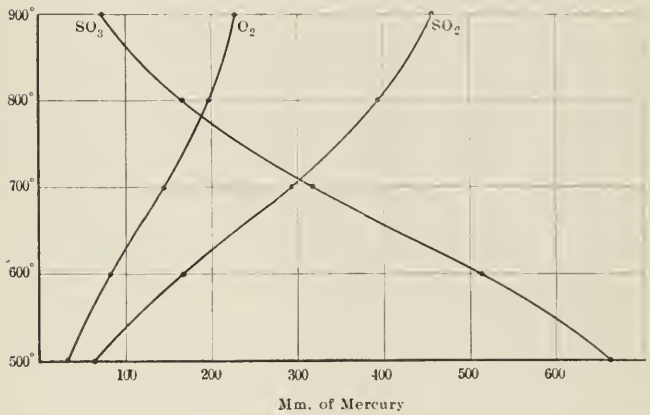

FIG. 2—COMPOSITION OF SO_3, SO_2 AND O_2 EQUILIBRIUM MIXTURES RESULTING FROM DISSOCIATION OF SO_3 AT ATMOSPHERIC PRESSURE

from the dissociation of sulphur trioxide at various temperatures under a pressure of one atmosphere (760 mm. of mercury) have been calculated. They are given in Table IV, and are shown graphically in Fig. 2.

TABLE IV—COMPOSITION OF EQUILIBRIUM MIXTURES OF SO_3, SO_2, AND O_2 EXPRESSED IN MM. OF MERCURY, THE TOTAL PRESSURE BEING 760 MM.

Temp. C.	P_{SO_3}	P_{SO_2}	P_{O_2}	$\frac{P_{SO_3}}{P_{SO_2}}$
500°	663	65	32	10.2
600	517	162	81	3.19
700	322	292	146	1.11
800	170	393	197	0.433
900	75	457	228	0.164

An important point to be considered in connection with the reaction under discussion is that of reaction velocity, which determines the length of time required for a mixture of the gases to react and produce equilibrium conditions. The time required depends, of course, upon the original concentrations of the reactants and upon the temperature. The effect of temperature in this case, as in most others of its kind, is to accel-

erate the reaction rate at the higher temperatures. But aside from these factors there is another of even greater importance, namely, the effect of catalysts upon the reaction rate. It has been found that under given conditions of temperature, initial gas mixture, etc., the reaction will proceed to equilibrium conditions at a greatly accelerated rate when the gases are brought into contact with such substances as platinized asbestos, and that various metal oxides, notably ferric oxide, affect the reaction velocity in a similar manner but to a lesser degree.[4] The catalyst does not alter the conditions of equilibrium, these being determined by the temperature and the partial pressures of the reacting substances; and in general the catalyst has an equal effect upon the reaction velocity, whether the direction of the reaction happens to be toward the formation of sulphur trioxide or toward its decomposition.

To return to the question of the metal sulphates, numerous investigations have been conducted to determine the conditions under which the common sulphates are formed and decomposed in the roasting furnace. An interesting and instructive piece of work is that of Wöhler, Pluddemann and Wöhler,[5] who determined the equilibrium conditions of several sulphates over considerable ranges of temperature. Their method consisted of heating the sulphate in an evacuated tube at constant temperature and measuring with a mercury manometer the maximum pressure of the gases evolved. Platinum sponge was placed above the sulphate to insure the rapid attainment of equilibrium conditions within the heated space. Hence the pressure measured was that due to the equilibrium mixture resulting from the dissociation of the sulphur trioxide evolved by the sulphate. The partial pressure of the sulphur trioxide in this mixture represents the dissociation tension of the sulphate at the prevailing temperature. The total pressures of the sulphur oxides and oxygen at various temperatures above the sulphates of metallurgical interest that were studied in the Wöhler-Pluddemann experiments are collected in Table V. These data have been plotted to scale in Fig. 3.

Table V—Total Pressures of SO_3, SO_2, and O_2 Above Sulphates

707	715	.....	.....	.....	.....	.....	.....	.....	.....

From the foregoing figures the equilibrium pressures of sulphur trioxide corresponding to various temperatures may be calculated for each of the sulphates listed by means of the equation,

$$\frac{p_{so_3}}{(p_t - p_{so_3})^{3/2}} = 0.385\, K_1.$$

For example, at 650 deg. the total equilibrium pressure of the sulphur oxides and oxygen above copper sulphate is seen to be 105 mm. See Fig. 3. Substituting 105 for p_t in the above equation and substituting for K_1 its value as given in Table III yields the relation,

$$\frac{p_{so_3}}{(105 - p_{so_3})^{3/2}} = 0.385 \times 0.178.$$

Solving this equation by trial shows p_{so_3} to be 37.7 mm. By this method the equilibrium pressures of sulphur trioxide above the different sulphates have been calculated for various temperatures. The calculated values are given in Table VI, and they have been plotted against the corresponding temperatures in Fig. 4.

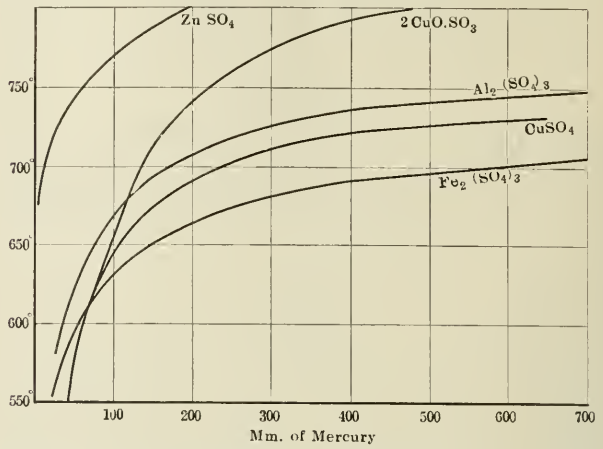

FIG. 3—TOTAL EQUILIBRIUM PRESSURES OF SO_3, SO_2 AND O_2 ABOVE VARIOUS SULPHATES

There are thus provided in convenient form the known facts concerning the equilibrium of a few of the metal sulphates and oxides with sulphur trioxide. It is unfortunate indeed that other sulphates have not been studied in a similar manner, but the data thus provided are useful in indicating the general relationship between temperature and the pressures of sulphur trioxide necessary to effect the formation of sulphates or to allow their decomposition.

Table VI—Dissociation Tensions of Sulphates at Various Temperatures, Expressed in Mm. of Mercury

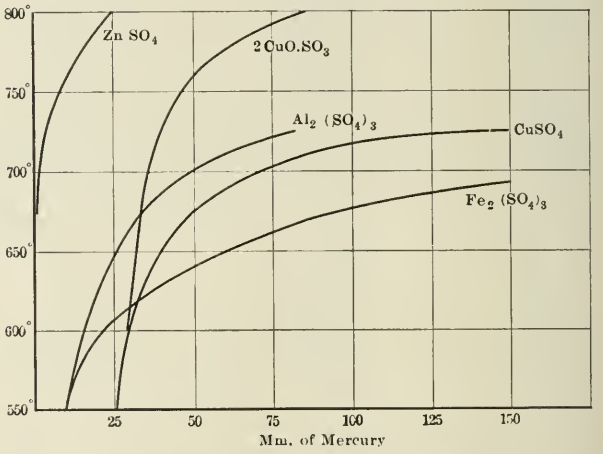

FIG. 4—DISSOCIATION TENSIONS OF VARIOUS SULPHATES WITH RESPECT TO SO_3

In general, the shape of each curve shows at first a slow increase of dissociation tension as the temperature increases. Then the increase in dissociation tension

[4] Knietsch, loc. cit.
[5] *Ber. der Deut. Chem. Ges.*, XLI, pt. 1, p. 703, 1908.

with temperature becomes more marked, and finally a comparatively slight change in temperature produces a very great change in the dissociation tension. The question of the order of decomposition of a mixture of metal sulphates is seen to depend somewhat upon the sulphur trioxide pressure in contact with them, the order at low pressures being in some cases reversed from that at higher pressures, as is shown by the crossing of the dissociation tension lines on the diagram, Fig. 4.

The properties of ferric sulphate, as shown by the curve representing its dissociation tension, deserve special mention. It will be noted that the dissociation tension of this compound is low at the lower temperatures shown on the diagram, but increases more rapidly with increasing temperature than is the case with the other sulphates shown. Since in the roasting furnace pyrite is one of the first sulphides to be ignited and oxydized, ferric oxide or the magnetic oxide of iron is produced at comparatively low temperatures. Owing to the low dissociation tension of ferric sulphate at low temperatures, it is to be expected under the circumstances that this sulphate will be the first to form. With increasing temperature, however, the dissociation tension of the ferric sulphate increases much more rapidly than that of the other sulphates. Consequently, although it may be the first to be formed, the ferric sulphate will in general suffer decomposition at lower temperatures than the other sulphates.

In viewing the subject of sulphate formation and decomposition from the standpoint of the equilibrium conditions of the reactions it must be remembered that it is very difficult, if not impossible, to predict or even to determine the magnitude of the sulphur trioxide concentration in contact with the ore at any time. This much, however, can be said: The concentrations of the sulphur oxides in the gas in immediate contact with the ore and in the interstices of the ore bed are greater than is shown by the analysis of the furnace gas as a whole. Also the composition of the gas in the interstices approaches that of the furnace gas as the depth of ore bed decreases and as the rapidity of rabbling increases.

From the foregoing discussion it follows that the formation of sulphates in the roasting furnace is promoted by low temperature, thick beds of ore, and slow rabbling; and that the reverse conditions will in general prevent the formation of sulphates or at least assist in their decomposition once they are formed. In particular it should be noted that a sulphate does not have a definite temperature of formation or of decomposition any more than water has a definite boiling point, the one being as dependent upon the sulphur trioxide concentration in the space surrounding the sulphate as the other is dependent upon the atmospheric pressure above the water.

Another important and useful investigation of the properties of the metal sulphates is that of Hofman and Wanjukow.[7] In their experiments a small amount of the sulphate contained in a porcelain boat was introduced into the horizontal tube of an electrically heated furnace, through which was passed a current of dry air. The temperature of the furnace and its contents was gradually raised, and observations were made to determine the temperature at which the sulphate begins to dissociate. In this manner the sulphate is subjected to conditions that resemble to a certain extent those obtaining in the roasting furnace.

Since in these experiments only small amounts of the sulphate (usually 0.3 g. of the crystalline salt) were worked with, the depth of the layer of sulphate in the boat was slight. With a fairly rapid current of air through the tube the partial pressure of the sulphur trioxide in contact with the surface grains of the sulphate was maintained at a low figure; though the same cannot be said of the conditions surrounding the grains of the lower layers. It is to be expected, however, that under the conditions described signs of decomposition of the sulphates will become evident at temperatures corresponding to low dissociation tensions. That this is in general the case may be seen by comparing the figures of Table VII with the curves of Fig. 4.

TABLE VII—DESULPHATIZATION OF ANHYDROUS METAL SULPHATES—HOFMAN AND WANJUKOW

Metallic Sulphates	Temperature of Beginning of Decomposition, Degrees C.	Temperature of Energetic Decomposition, Degrees C.	Products of Decomposition	Remarks

$CaSO_4$	1,200		CaO	White
$BaSO_4$	1,510		BaO	White

In determining the temperatures specified above the investigators obtained evidence of decomposition in the following manner: The furnace containing the sulphate under investigation was heated slowly by passing an electric current of constant strength through the resistance coil. Data for a temperature-time heating curve of the furnace were obtained by making temperature observations at definite time intervals, the position of the junction of the thermo couple, with which the observations were made, being near the surface of the sulphate contained in the boat. Since the dissociation of a sulphate is an endothermic reaction, the curve plotted from such data will show a jog when the rate of decomposition of the compound becomes sufficient to make evident the thermal effect in this manner. Also the gases issuing from the furnace tube were tested by suitable indicators for sulphur trioxide and sulphur dioxide.

The figures given in Table VII represent, therefore, simply the temperatures at which decomposition under the existing conditions could be identified by the means employed. In fact, in many cases, due to slight evidences of dissociation at lower temperatures than those specified, considerable latitude was left to the observer in his decision as to just what temperature corresponds to the beginning of decomposition at a practically important rate. Consequently the figures given, while of great value because they represent temperatures at which the various sulphates are decomposed at a fairly uniform rate under certain conditions determined by the method of the experiments, do not necessarily represent the minimum temperatures at which the sulphates undergo decomposition. Nor do these figures necessarily represent the temperatures at which the respective sulphates are decomposed in the roasting furnace, the temperature of decomposition being in each case a variable as has been explained in a preceding paragraph.

To summarize, it may be said that the decomposition temperatures thus determined are dependent to a great extent upon the rates of decomposition of the different sulphates under the conditions existing at the time of the experiments. This brings up the question of reaction velocity in heterogeneous systems and the factors and conditions upon which it depends. These are of im-

[7] T. A. I. M. E., XLIII, 523, 1913.

portance, because, from a practical viewpoint, it is of little use to know that a reaction may take place but at so slow a rate as to render its effects imperceptible.

Metallurgical Smoke

The U. S. Bureau of Mines has recently issued *Bulletin* 84, by Charles H. Fulton, setting forth in "plain and simple English" the facts regarding metallurgical smoke and its treatment. The pamphlet contains much valuable information, including data on operating plants and illustrations of various methods for controlling smoke production.

As showing the tremendous volume of smoke that may be produced at a large smelter, the following data

Table I—Part of Flue System

Constituent	Flue from roasting furnaces	Flue from blast furnaces	Flue from converters	Flue from reverberatory furnaces	Flue at base of stack
Sulphur dioxide	2.545	1.274	2.845	4,423	1.164
Sulphur trioxide	0.275	0.086	0.0505	0.0044	0.0395
Carbon dicxide.	0.1136	6.493	0.2084	5.242	2.748
Water vapor...	2.784	3.490	1.061	3.869	2.834
Arsenic trioxide	0.0073	0.0091	0.00073	0.0156	0.00465
Oxygen	14.02	10.18	12.04	10.37	11.88
Nitrogen	81.18	78.13	83.64	79.57	80.73
Carbon monoxide	None	None	None	Trace	None
Total	100.90	99.70	99.80	99.50	99.40

are given on the Anaconda smelter. The stack discharges 1,341,000,000 cu. ft. of smoke per 24 hours, containing about 1.734 per cent by volume of sulphur dioxide, equivalent to 3427 tons of sulphuric acid.

The composition of gases from a typical Western copper smelter, in percentage of volume at 0 deg. Cent. and 760 mm pressure, is given as follows:

The dust and fume losses at smelting plants reaches a magnitude that would not be suspected unless thoroughly investigated. Thus at Great Falls with the old flue system in use it was demonstrated that there was a daily loss in dust of 3775 lb. copper, 106 oz. silver and 0.71 oz. gold. With the new flue system this was reduced to 347 lb. copper, 28.5 oz. silver and 0.2 oz. gold. The saving effected was $372 a day by a flue system that cost $1,100,000. At the Copper Queen plant there was a daily loss of copper in dust amounting to between 6000 and 18,000 lb. copper, depending on the number of furnaces in use.

The *Bulletin* discusses methods of recovering fume and dust from smelter smoke, and describes and illustrates different flue systems, bag houses and electrical precipitation apparatus. It also covers the manufacture of sulphuric acid from smelter gases and describes the work at the Tennessee smelters. The Hall and Thiogen processes for recovering sulphur from roasting ores are briefly described.

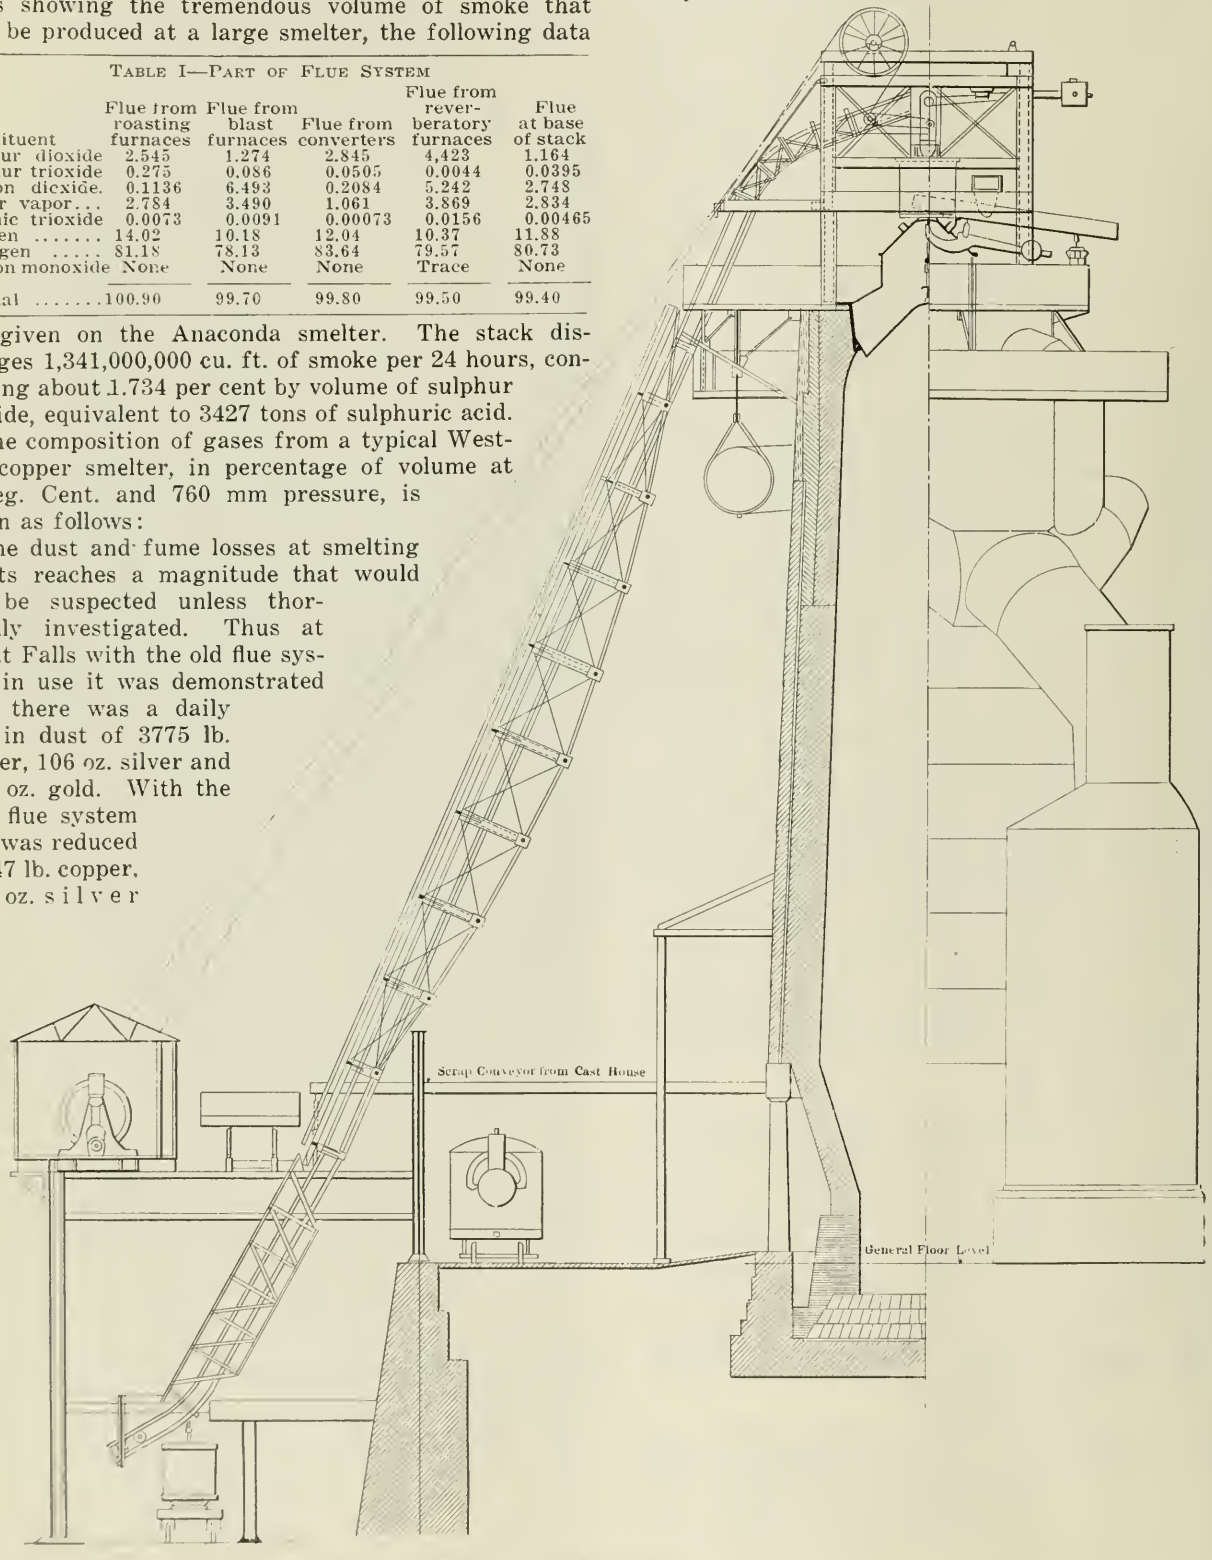

FIG. 22—GENERAL ARRANGEMENT OF NEELAND TOP

Filling the Blast Furnace

BY J. E. JOHNSON, JR.

(*Concluded from page* 173)

The Bucket System of Distribution

When the Duquesne furnaces were designed, as I have previously explained, practically all the traditions of blast furnace design were discarded and the engineers struck out on lines boldly new in almost every direction. This was true in regard to the filling system which was invented for that plant by M. A. Neeland, then chief engineer of those works.

When the plans for the plant were started there were only two mechanically filled furnaces running, one with the Brown top at Sharon, previously mentioned, and one with the upper hopper closed by an orange peel at the Lucy furnaces which their superintendent recommended be *not* adopted.

A set of drawings for a skip-filling system had been made, but when Mr. Rotoff (since deceased) came to the plant to be superintendent of the furnaces which it was proposed to build, he rejected this design absolutely as he had had experience with some very unsuccessful skip-filled furnaces at the Isabella plant where the segregation of the lumps and fine had manifested itself very clearly and had demonstrated how completely it could prevent the satisfactory working of the furnace.

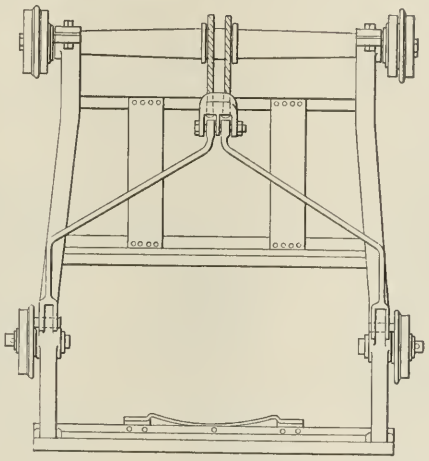
The top now to be described was designed by Mr. Neeland to overcome this difficulty, and it has been very successful in doing so. To accomplish this result he decided to use a type of bucket for hoisting the material which could be accurately centered on the furnace top before dumping, and then be dumped uniformly in all directions.

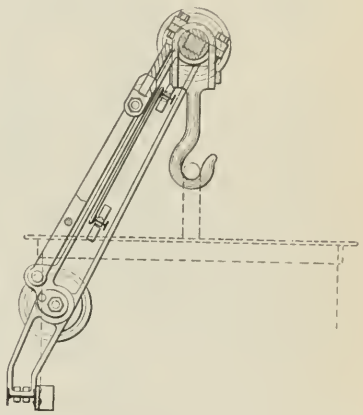
The huge bucket used has its bottom closed by a bell by the central rod of which the whole is suspended from the truck which ran on the inclined hoist. The general arrangement is shown by Fig. 22 (p. 226).

The scale cars on which the buckets are set run along under the double row of bins from which the buckets are charged with the required material. Each bucket in turn is then brought into the central plane of the skip where it is picked up by the hook on the inclined truck (Figs. 23 and 24) and carried to the top of the furnace. There the front end of the truck with the bucket hanging to it enters a vertical slide in the center line of the furnace top and is lowered vertically to a seat on the top of the gas seal. The further downward movement of the slide lets the bell bottom of the bucket pass down inside the gas seal carrying the counterweighted gas seal bell with it. The bucket then discharges and the return movement of the slide raises the bell-bottom of the bucket back to place, allows the gas seal to be sealed by its counterweight, and finally picks up the bucket itself on its own bell, and the return trip of the truck takes it back to the bottom where it is unhooked and another loaded bucket picked up. The arrangement is well shown by Figs. 25 and 26 which show the bucket resting on its seat in the furnace top and its bell on top of the gas seal bell.

It will be seen that there is no horizontal velocity whatever to the stock, and that if it is reasonably level in the bucket an equal amount is discharged on each sector of the bell. It is, in fact, as if the hopper of the double bell top were filled under the bins brought up to the top of the furnace and dumped, instead of being filled by the intervention of the skips. It is worthy of note that the bins are arranged in parallel rows on each side of the scale car tracks so that the buckets are filled alternately from opposite sides thus balancing up the irregularity which would have arisen from the great segregation on one side of the bucket had it been filled always from one side. At the same time it is no more than fair to add that Mr. Neeland had this matter of segregation very much in mind and he designed the bins with the shortest possible chutes to give a low delivery velocity and so arranged that the stream of material strikes as closely as possible on the apex of the bell bottom of the buckets.

In more recent years this system of filling has been improved by the addition of a motor on the scale truck which rotates the buckets either through a certain definite angle after they have been filled, increasing by a fixed amount for each bucketful, as for instance 90, 180 and 270 deg., or else the buckets are rotated continuously while charging, so that the charge may be distributed in uniform rings thus securing an equable distribution of lumps and fines in every portion.





FIGS. 23 AND 24—BUCKET CARRIAGE OF THE NEELAND TOP

Ford-Parkes Top

Various modifications of this type of filling system have been made. A general drawing of the Ford-Parkes design was shown in the second article of this series. The details of the top and bottom are shown by Figs. 27, 28, 29 and 30. The buckets in this design are not delivered onto a scale car, but onto a turntable carrying four bucket seats. This table is rotated 90 deg. at a time, and this rotation takes the empty bucket away and brings a freshly filled one to take its place. When the bucket is at 180 deg. from the position under the skipway, it is filled from the scale car which in this case is the regular hopper type of scale car. The general arrangement of the turntable and the motor for turning it are also clearly shown, also the scale car in position in Fig. 28.

The general design of the bucket-carrying truck is shown at the foot of the incline, the large quadrant at the front or upper end of the truck from which the pick-up hook hangs is clearly shown. This quadrant is rigidly attached to the rear wheel of the truck and pivoted on its own center in the center of the equalizer between the two front pairs of wheels. It is evident that if the rear wheel of the truck be swung up around the pivot as a center, that the hook carried by the chain

unwinding from the quadrant will move vertically downward.

Referring now to Fig. 30, showing the top of the incline, there will be seen the convex curve on which the two front pairs of wheels of the truck run, and above a guiding slot with a sharp reverse curve which acts as a guide for the rear pair of wheels. The upper portion of this guide is a circle struck from the center of the truck in its top position, and this circle permits the rear wheels of the truck to rise while holding the pivot of the quadrant rigidly in its place, and gives the required vertical movement to the bucket as a whole. This seats the bucket on top of the gas seal exactly as is done with the Duquesne top, but without the assistance of the vertical slide, and therefore somewhat more

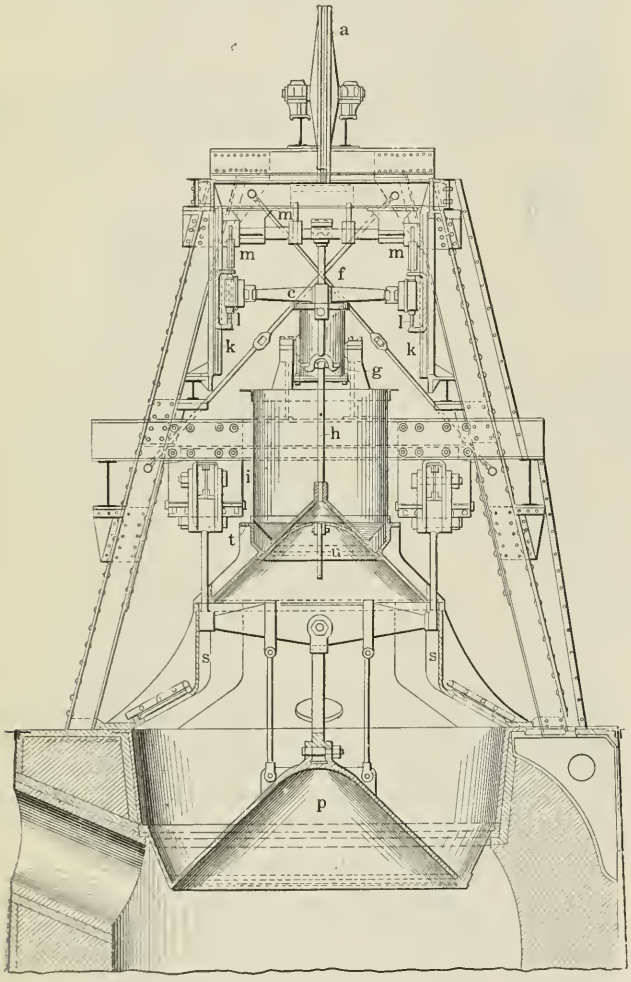


FIG. 25—DETAILS OF NEELAND TOP

simply. The return of the rear wheels to their normal position is secured by a heavy counterweight which the rear wheels pick up just before they enter the guide, and which pulls them back down on to the incline as soon as the hoisting rope is slacked. The head-shieve is clearly shown just above the curved guide.

Other modifications of this type of top have been built but the principle is no different from those illustrated in any of them.

At one of the most successful plants in the country the bucket is never unhooked from the carriage but rigidly attached to it just as the skip is attached to the hoisting rope, but provision is made for rotating the skip on its vertical axis to each of three equally spaced directions in turn, this eliminating irregularities in the charging of the skip.

It will be seen that this type of filling gives precisely the same type of distribution as the doube-bell type of top, and with almost the same limitations. That is to say, irregularities due to the way in which the charge is delivered into them may and generally do occur with either type of filling, and may be more or less completely compensated by the correct rotation of the receiving part to the different dumping points in regular order.

At the same time it must be recognized that the advantage is with the bucket system if the top be not rotated because of the smaller number and lower velocity of transfers of the stock with corresponding reduction of the opportunity for segregation.

Guiding the Bell Movement

One point of extreme practical importance in all types of furnace tops is the path of the main bell in its descent. It is obvious that if it be attached directly to the end of the bell lever the latter swinging as it does in the arc of a vertical circle will carry the bell in a similar path and it will be either one side or the other of the center of the furnace, in the plane of its motion, practically all

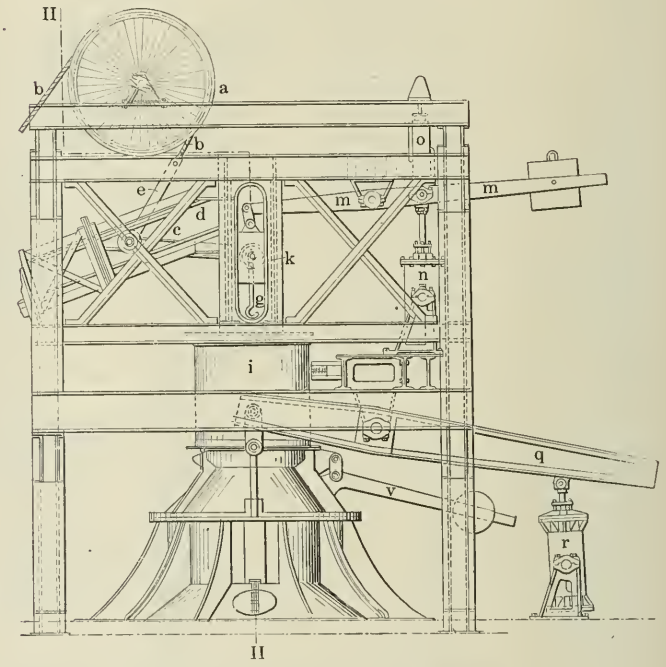

FIG. 26—DETAILS OF NEELAND TOP

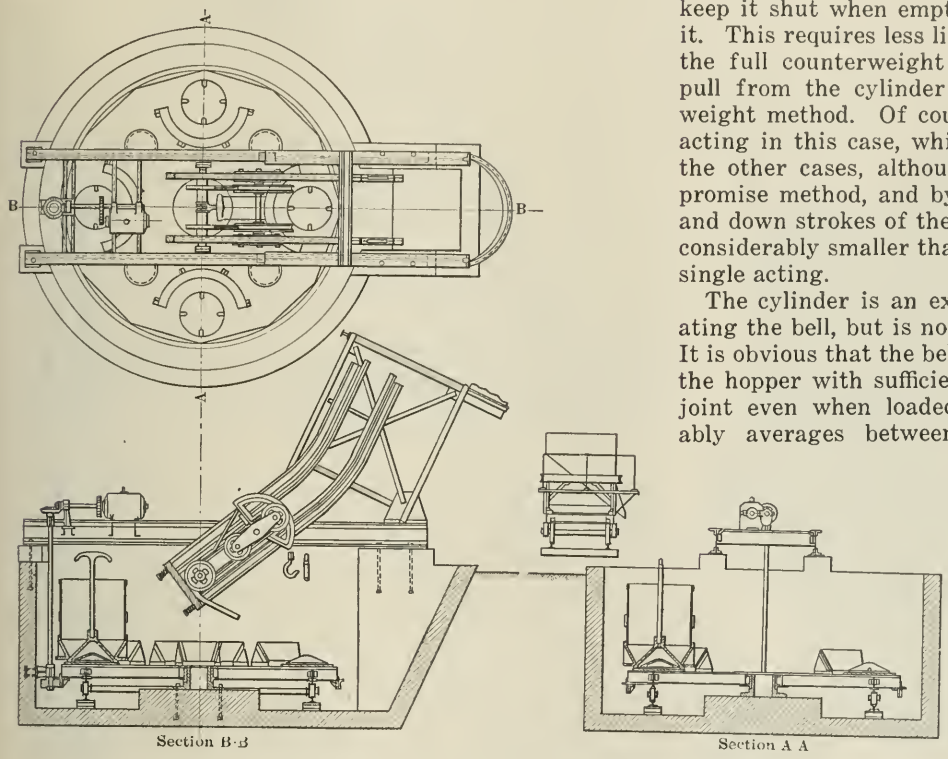
the time. The projecting end of the bell lever is quite long, and it looks as though the curvature of the path described by it could be ignored, but this is by no means the case. The versed sine of the arc described always amounts to a couple of inches and may easily exceed this, which is enough to insure there being a considerably greater portion of the charge on one side of the furnace than on the other, and much bad furnace work has been attributable to this irregularity. The path of the bell rod must always be a straight line exactly in the center of the furnace. This straight line can be produced either by a rigid guide for the bell rod, connecting the latter to the lever with a short link; a quadrant from which a flexible suspension member unwraps always in a vertical line as the lever rises and falls, or a mechanical parallel motion similar to that of Watt's steam engine. A good illustration of the quadrant system is shown in Fig. 10, in which the bell is suspended from the triangles which are hung from chains working in grooves in the castings on the ends of the bell lever, these being segments of circles concentric with the center of the lever.

The parallel motion design is well shown by Fig. 12. The bell rod is not connected directly to the end of the

main bell lever but to a short link which projects above it, the upper end of which is guided by a connecting link pivoted to a projection on the fulcrum of the main bell lever. The proportions are such that the bottom point of the suspension link where it is attached to the bell rod moves in an absolutely straight line. In Fig. 12 the small bell is guided by the main bell rod and therefore is not provided with any parallel motion, only with a suspension link to connect the curved movement of the bell lever with the straight-line movement of the bell rod. But in many cases the lever of the small bell is provided with its own parallel motion also. The rigid guide is used on the Baker top, the (two) bell rods passing through guide castings riveted to the gas seal and others on the superstructure at the upper end of the rods. The bell-lever is connected to the rods by a short link as shown (but not very clearly) by the drawing.



FIGS. 27, 28 AND 29—BOTTOM OF FORD-PARKES SYSTEM

Bell-Operating Apparatus

In the early days of the closed-top furnace the bell was probably always controlled by a hand-operated "crab," consisting of a crank and connecting rod driven by gearing. A large gear having a crank pin in its face was set immediately under the outer end of the bell beam and a connecting rod ran from a pin in the bell beam to the crankpin in the gear. When the pin was in its lower position the bell was shut, and the travel of the pin was such that when it was in the opposite position the bell was opened wide. A few of these crabs have remained in operation down to quite recent years, but they were superseded in general practice many years ago by a steam cylinder as shown in several of the preceding figures.

There are two methods of using the cylinder. One is to counterweight the bell so that it will stay shut even with the full charge upon it, and have the cylinder lift the counterweight to open it. This has the great advantage that if the steam connections are broken or any other mishap takes place, the bell remains closed and prevents the entrance of air into the top of the furnace, which is necessary in order to prevent gas explosions.

In the other method of operating, the counterweight is dispensed with and the direct downward pull of the cylinder keeps the bell closed. This is somewhat simpler than the other method or at least permits doing away with the counterweight; moreover by operating in this way the cylinder can be placed at or near the bottom of the furnace and connected with the bell by means of a wire rope, but obviously this cannot be done when the bell is kept shut by a counterweight. However, a counterweight can be applied at the bottom of the rope and immediately over the top of the cylinder if desired.

In some cases a compromise method is used and the bell is counterweighted about to the extent which will keep it shut when empty but not with the charge upon it. This requires less lift from the cylinder to open than the full counterweight method, and also requires less pull from the cylinder to close than the non-counterweight method. Of course the cylinder is made double acting in this case, which it need not necessarily be in the other cases, although it usually is. By this compromise method, and by equalizing the work on the up and down strokes of the cylinder, the latter can be made considerably smaller than when it is virtually or actually single acting.

The cylinder is an extremely simple method of operating the bell, but is not a particularly satisfactory one. It is obvious that the bell must be held to its seat against the hopper with sufficient pressure to make a gas-tight joint even when loaded with the charge which probably averages between fifteen and thirty thousand pounds. The amount of work involved in opening and closing the bell is very small, and in order to be large enough to hold the bell shut or push it open by direct action the cylinder must be much too large for the real work it has to do, in order to form a satisfactory lock in holding the bell shut with the charge upon it.

On the other hand, any mechanism which exercises a reasonable control over the bell during the dumping operation and likewise in closing so as to prevent excessive velocity is practically sufficient, except in the case of the full counterweight method.

It is very desirable to have a relatively slow movement of the bell at opening and closing so as to prevent slamming and violent inertia shocks on the whole mechanism. For this purpose the bell cylinders are piped as shown in Fig. 19. Inlet takes place through the pipe next the end of the cylinder, but discharge can only take place freely through the one further in from the end, since the outer one contains a check which prevents return flow, at any but a very slow rate, so that when the piston overruns the outer port it is cushioned by the steam trapped between that and the head of the cylinder, and its velocity thus checked at a rate slow enough to do no harm.

The cylinders generally require to be operated by steam as compressed air for such purposes is expensive and is likely to be frozen up in winter. When the bell cylinder is placed at the top of the furnace great care must be used to prevent the pipes leading to it from being frozen since there is no flow except when the bell is operated, and in severe weather during a relatively short suspension of filling a sufficient interval may occur between piston movements to permit this to occur.

It will be seen that the crank and connecting rod has an absolutely smooth acceleration and retardation and that in the closed position it acts like an inverted toggle and holds the bell tight shut without expending any energy on it, so that it furnishes the ideal movement for this purpose. To make use of this ideal motion and to dispense with the necessity of steam or compressed air for operating bell cylinders an apparatus has been brought out in recent years which returns to the crank and connecting rod principle; but instead of being hand operated, as the earlier ones were, it is driven by an electrical motor controlled by automatic switches. The design brought out by the Otis Elevator Company is shown in Fig. 31. Fig. 32 on a smaller scale shows the arrangement of the crank in relation to the gear more plainly. The motor drives worm gears enclosed in the housing shown, and these in turn drive an internal pinion which meshes with the teeth of the annular gear. Automatic switches practically identical with those illustrated in connection with the furnace hoists control the movement of the apparatus. When the starting switch is closed the motor starts and runs until it has driven the main gear and the crank through a complete revolution, when it is automatically slowed down and stopped. This obviously opens the bell and closes it again. The only objection to this apparatus is its very considerable cost, and the necessity of having such an amount of machinery at the top of the furnace.

It may be said that while the cylinder has its disadvantages for operating bells, with certain modifications it could be made to do very much better than the direct acting cylinder, and in many ways almost equal to the expensive electrically operated apparatus without costing nearly so much.

The operation of gas seal bells is practically the same as that of large ones, although it requires very much smaller apparatus, since the loads to be carried are very much smaller and the small bell itself also weighs many hundred pounds less than the large one. In some cases now the upper bell is operated by an electrical bell hoist similar to but smaller than the one illustrated, for of course it is desirable to have both types of mechanism the same, to have either both steam or both electric.

These bells have generally been operated by cylinders working through levers the same as those used on the main bell, but several years ago Julian Kennedy of Pittsburg brought out a design in which the cylinder for the small bell was placed immediately over it in the center of the furnace in an inverted position, its piston rod becoming the rod of the small bell. This, of course, dispenses entirely with the lever for transmitting the motion, etc., but is open to the objection that steam must be on the cylinder practically all the time in order to keep the bell shut, or else a counterweight and lever must be used.

This design is followed with the riffle-barrel cylinder of the Baker top as already noted, but in that case the normal position of the small bell is open, so the cylinder is only under steam when the bell is being raised to close and rotate it.

Provisions for Access and Repairs—Means for Hoisting Main Bell

In the days when furnaces were hand filled and practically the only mechanism on the top was the single bell with its lever and bell cylinder, considerations of accessibility played no part, there being but little apparatus and that all in plain sight. When a bell had to be taken down from the top of the furnace or sent up it was hoisted out with some simple but powerful hoist; set on rails and skidded over to the platform of the hoist, commonly known as the cage, on which it was lowered

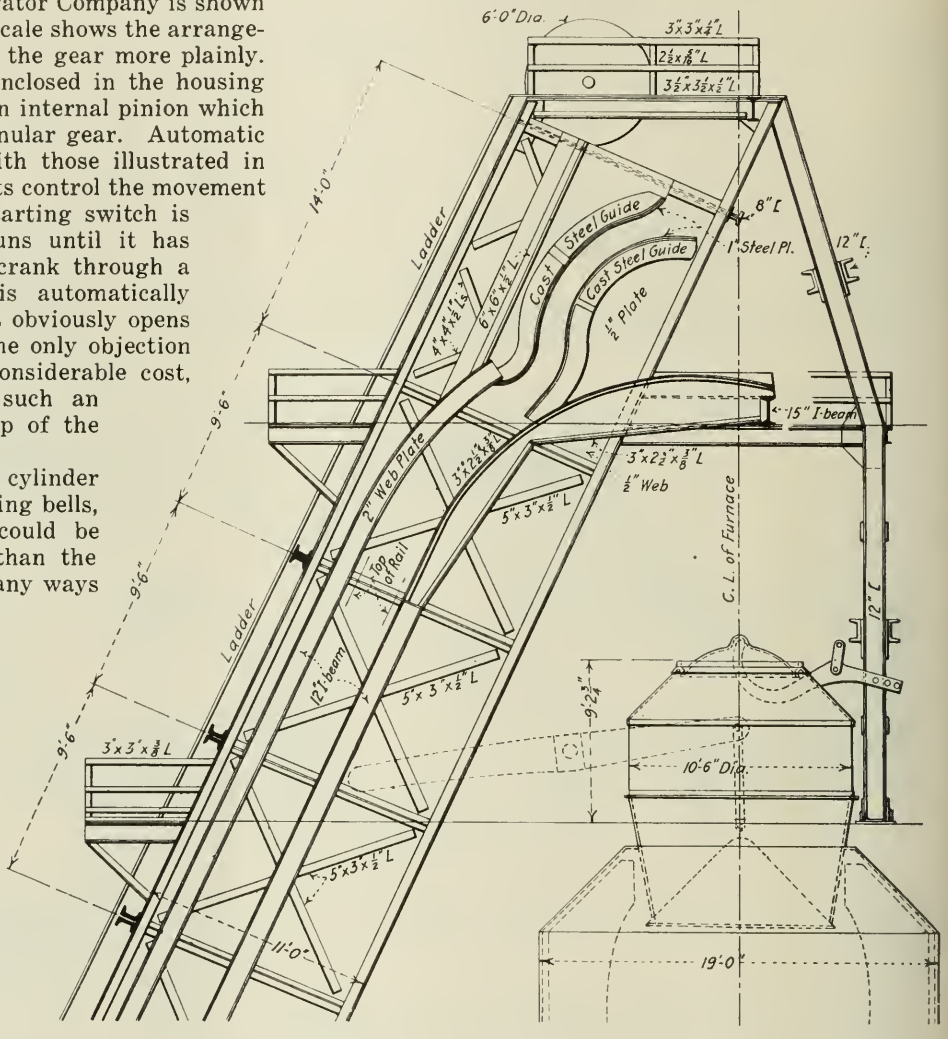


FIG. 30—TOP OF FORD-PARKES SYSTEM

to the bottom and a new one to replace it was brought up in the same way.

With the mechanical top all that is changed. There is in all cases a considerable quantity of machinery and in many designs a vast amount. This is erected when the furnace is built and is never expected to be removed until the furnace itself is torn down. The main bell is not only at the bottom of a hopper in many cases deeper than the height of a man, but is covered over by an air-tight gas seal so that access to it is most difficult even for inspection, while before any repairs can be made a considerable portion of the top must be dismantled.

This is a point which has been too little considered in the design of furnace tops. Some engineer in a cool and pleasant drafting room designs some form of apparatus which pleases his fancy, and which may then be built easily enough because its construction is fundamentally no different from that of any other mechanical apparatus. But when the repairs become necessary

they are turned over to the operating man, and must be made under circumstances which may be conservatively described as follows:

The temperature of every part that needs to be handled is high enough to burn the hand, in many cases so hot that the radiation makes it disagreeable to approach. Every crack and cranny is filtered full of dust that at the best is packed tight, and if it has been rained on is cemented almost as hard as iron. The air is not only heated almost to the point of suffocation in many cases, but in practically every case is mixed with furnace gas containing 25 per cent carbon-monoxide, of which 1 per cent in the atmosphere is quickly fatal, and a small fraction of a per cent causes violent sickness. The nut of every bolt is either burned or rusted fast, or so jammed with dust that it will move but one "flat" at a time, and often will not start at all except with a sledge hammer and chisel. The room available on the top platform is generally just sufficient to permit bare access around the top of the furnace when everything is in place. The little space in which one might move with safety or speed is seized for the storage of parts as soon as the top is dismantled for access to the bell and hopper.

Under these circumstances it would seem as though some consideration might be given to accessibility and to designing some of the parts, notably the gas seal, so that they would go to place and function properly without the necessity of coming to an exact position, something which it is almost impossible to make them do after all this machinery has been subjected to the heat if not flame which are unavoidable at the top of a furnace, but this point appears to have been given very little consideration.

In quite a number of types the gas seal which rests on the lip of the main hopper supports the distributor; this means that in order to change bells the whole distributor must be taken off and the gas seal completely dismantled before the real work of removing the bell can be started.

It will perhaps illustrate the operating man's point of view to explain the former method of holding the lip ring down to its seat in the hopper. This was almost universally done with square bars resting against the lip ring at the bottom and passing through a socket near the top of the hopper, a key in a key-way through the bar just below the socket was driven by a sledge so as to force the bar down against the upper edge of the lip-ring, thus holding it to place. It is obvious that when the lip ring became loosened by the constant jar of the bell in closing, these keys could only be tightened by putting a man into the gas seal through a manhole such, for instance, as that shown in Fig. 12, and having him drive up the keys.

It will be seen that he had to stand in a V-shaped space without a particle of footing, the temperature under the seal in many furnaces is seldom much less than two hundred degrees, even if means have been taken to cool it off, while there is almost certain to be a certain amount of gas leakage through the main bell and no chance of obtaining adequate ventilation through the small man-holes in the gas seal. I have known of at least one case where a man was killed by gas on going in under the gas seal to do some such work. The gas was not in sufficient quantity to be visible, and several men were rendered unconscious by it before the damage was realized, but by quick work on the part of the master mechanic all were taken out alive except the one.

In course of time the operating men determined that the holding bars for the lip ring must be tightened from outside the gas seal, and changed the construction to permit this, a practice which is now almost universally followed. The general principle of the method by which it is done is shown on the left hand side of the hopper in Fig. 18.

Of course, neither the hoisting apparatus for the skip nor that for the bucket system of filling affords any possibility of handling the bells, and, therefore, some other provision must always be made for letting down old bells and bringing up new ones. This is very generally in the form of a runway extending well out over the side of the furnace, as shown in Fig. 12. In this case the runway is the same as that which carries the adjustable receiving hopper. When a bell is to be handled the hopper is removed and the trolley shown at the extreme left hand end of the runway is brought into action. This trolley runs far enough out so that the bell hanging from it in its outmost position clears the furnace entirely and may be brought up vertically; then when it is above the hand-rail the trolley is traversed over to

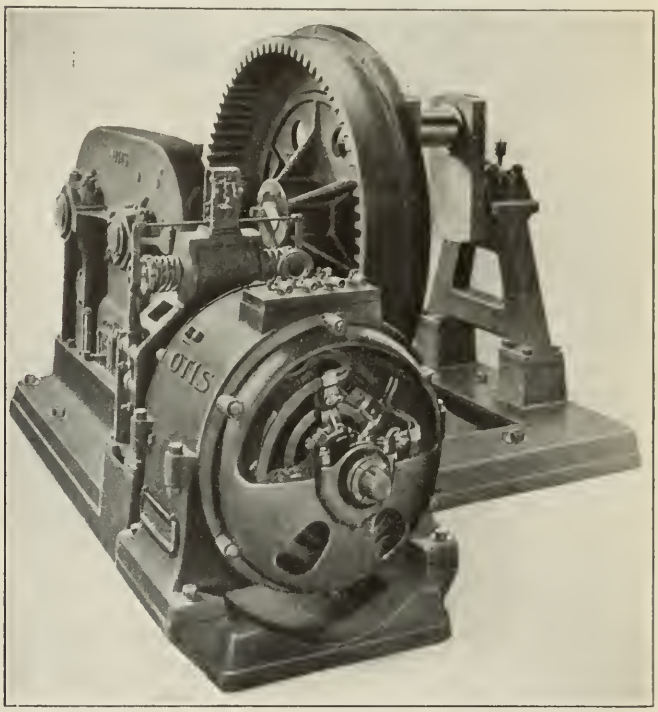

FIG. 31—DOUBLE SCREW INTERNAL GEARED ELECTRIC BELL HOIST, DIRECT CURRENT

the center of the furnace and the bell lowered into place. Sometimes a jib crane is used for this purpose, but in some cases within my experience these have been forced out of plumb by distortion of the furnace top and have been extremely hard to swing around, especially when under load. For this reason the runway with the traveler is probably much to be preferred. Ordinary hoisting arrangements cannot be used on the trolley on account of the great height of lift involved, and it is well to provide not only a trolley with its sheave, but to have some means of doing the hoisting quickly and safely.

Bells are certain to give out at intervals, probably their life does not average much over a year, and to have a good top design and good arrangements for hoisting and a top accessible without too much dismantling means the difference between a shut down of twelve and one of forty-eight hours.

The Stock Line Recorder

One of the most important points in connection with the filling of the blast furnace is to maintain the stock line at the proper height. With hand-filling this was frequently very difficult to do. The physical limitations of the apparatus, to say nothing of those of the men,

were such that if the furnace once "got down," that is if the stock line settled to a lower level than it should by the melting of the stock column below, it was very difficult to catch up as I have already explained. And if the stock line settles to the level which the stock should reach after it has been in the furnace for say two hours, then obviously the stock charged while that condition prevails is deprived of two hours of the time it should receive in treatment. This is frequently more than

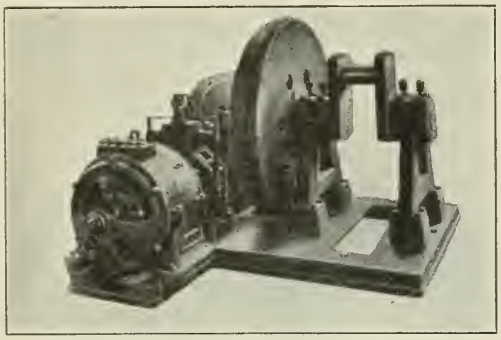

FIG. 32—BELL HOIST—CRANK END VIEW

enough to derange seriously the working of the furnace.

For this reason it is of great importance that the furnace shall not only receive in one twelve hours the complement of stock which it requires, but that this should be received at a uniform rate, and the stock line kept constantly within a very few feet of its proper position. When the furnace is filled with skips their capacity for handling materials is so vast that there is not often any physical obstacle to prevent the furnace from being kept full, but the very speed with which it may be charged may be a disadvantage since the men on the night shift may take a "spell" of an hour or two knowing that by hard work they can catch up by daylight, although the furnace may be "down" many feet when they begin to made up for the time lost, and its working deranged thereby.

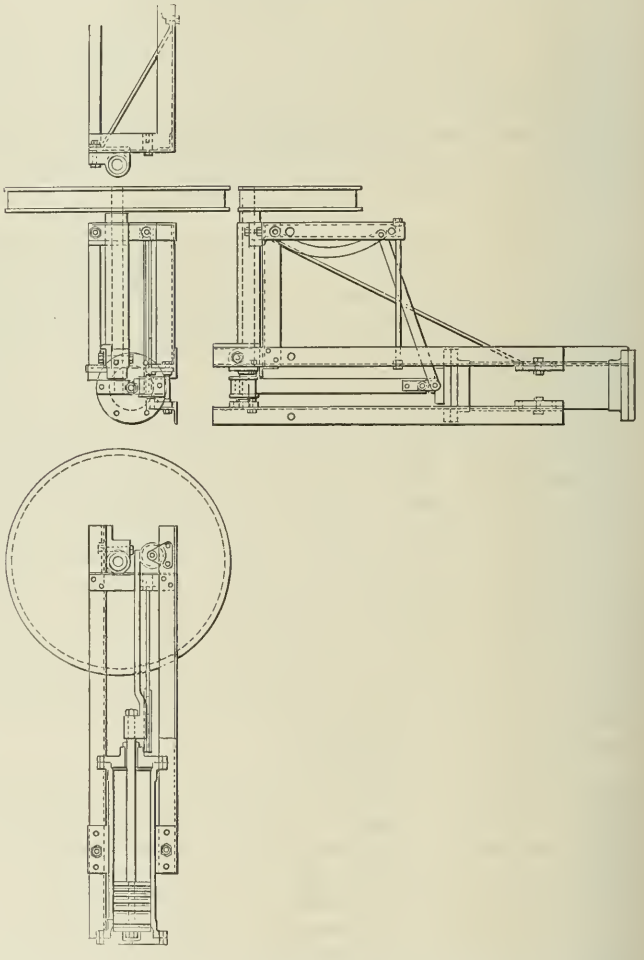
Gaging rods working through the top of the furnace, generally through the hopper or a point just back of its upper edge, have been provided ever since the introduction of the closed top, and in recent years since the introduction of skip-filling, arrangements have been made whereby the test rod is suspended from a rope which winds on a drum at the bottom of the furnace, and by operating this drum the furnace can be gaged without the necessity of going on top.

There is also another need to gage the stock line. This results from the fact that while the stock line ordinarily settles quite regularly, so many inches per minute, at times the furnace slips and the stock line will drop from two or three feet up to fifteen or twenty in moderate slips, and of course much greater depths in violent explosions and even though the furnace be working normally below it is much more desirable to have a record of the way the stockline is settling, so that any tendency to lag or work irregularly can be detected and cured without delay.

For the accomplishment of this purpose I designed several years ago an apparatus called a "Stock Line Recorder," of which the principle is very simple. (See Transact. *Amer. Inst. Min. Eng.*, Vol. XXXVI.) The test rod instead of being raised up out of action except when the furnace is to be gaged rests normally on the stock and settles with it. When the bell opens to admit the charge the test rod is drawn up out of the way, and when the bell closes it settles back on the stock in its new position, and follows it down until lifted for the next charge, and so on.

The mechanism by which this is accomplished is extremely simple, and the actuating portion of it is shown by Figs. 33, 34, 35. The test rod, which is made quite heavy, hangs in the furnace in the ordinary way. Light, flexible wire ropes are passed over a sheave on top of the furnace, and from thence to any convenient point, preferable near the skip operator's platform, where the actuating mechanism is placed.

The rope is wound on the narrow flanged drum, shown at the top in the plan view. This drum is keyed to a shaft, on the other end of which is keyed a small pinion meshing with a rack fastened to the piston rod of the cylinder shown below. The piston rod works through a metal gland with a fairly free fit so as to avoid friction. The piston is made quite heavy or else weight is attached to it in some way so that this weight acting through the pinion and drum tends to take up the slack from the test-rod rope, but on account of the much greater radius of action of the rope, and the considerable weight of the test rod, the weight of the piston alone cannot lift it. The top of the cylinder is connected to the main bell cylinder, generally without any valves or connections of any kind, so that when steam is turned on the main bell cylinder to open the bell it is simultaneously turned into the top of the recorder cylin-



FIGS. 33, 34 AND 35—OPERATING MECHANISM FOR STOCK-LINE RECORDER

der, and forcing the piston down raises the test rod to its highest or "safe" position.

When the steam is exhausted from the bell cylinder to close the bell it is simultaneously exhausted from the recorder cylinder, and the weight of the test rod with its greater leverage then lifts the piston in the cylinder until the test rod rests upon the stock, when it comes to rest and only moves thereafter as the test rod settles in following the stock down. The movement of the

mechanism is reduced by the lever shown in the back view (Fig. 34) and transmitted to the mechanical recorder, either of the dial or the strip type, and makes thereon a saw-toothed record as shown in Fig. 36. The amount of information obtainable as to the way the furnace is settling, whether steadily or by slips, is quite remarkable. One accustomed to the type of chart produced by a given furnace can tell by a glance at it whether the furnace is working normally or not, while the check on the fillers, on the human side, is an absolute one since it must work if the furnace is filled, and in a number of year's experience no method was ever found by which the machine could successfully be "beaten."

The subject of distribution is so vast, the number of variables and their reactions upon one another being practically infinite, and our knowledge of what the furnace really requires is so exceedingly limited, that the

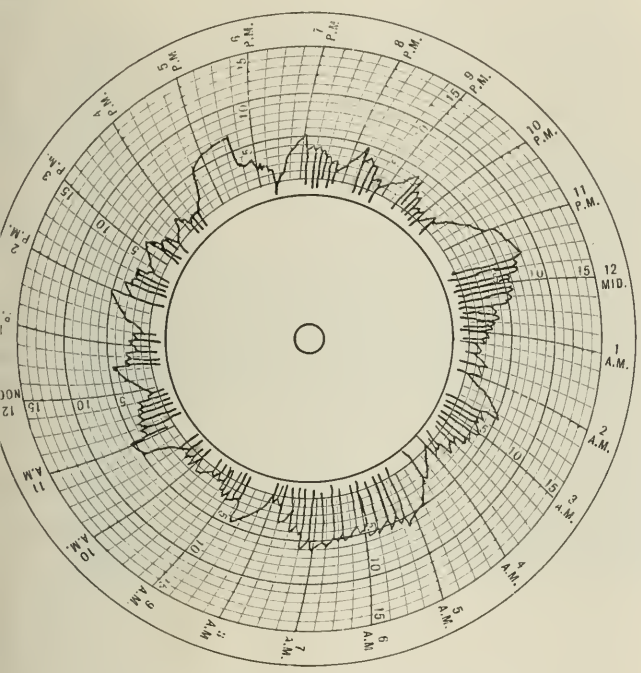


FIG. 36—CHART OF STOCK LINE RECORDER

little we know on the subject has only been developed by an utterly disproportionate amount of trial and experimentation, both with models and with furnaces, and by the slow process of elimination of the most unfit. It is probable that a book could be written upon the subject if one were willing to go back and compile the results of the experience of furnace men of the older generations.

But the question of whether we will or will not use mechanical filling for furnaces has been settled for us as have so many other questions, not upon the technical ground of whether its distribution is better than that of the hand-filled furnace, or the technical results better or worse than that of its predecessor, but by the stern law of necessity. The waning supply of men available for continuous heavy work, and the increasing wages which they command, combined with the absolute necessity of continuous operation irrespective of all other considerations, have forced us to adopt mechanical filling. There is no reason to believe that certain circumstances will ever alter so that large plants will be in a position to go back to hand-filling even if they should so desire.

It remains, therefore, only for us to use our best endeavors to find out the fundamental laws of distribution, and then to design an apparatus which will conform with those laws and survive under the conditions on the top of the furnace. These are that any apparatus placed there shall receive a scant inspection surely not oftener than once a shift; that a shut down for its repair or for overhauling will be tolerated certainly not oftener than once in six months; that it must operate twenty-four hours a day, and seven days a week; that it must practically always be almost at the limit of working temperature for ordinary machinery; that it must be not infrequently exposed to a much higher temperature and often to flame itself, and that it must work in an atmosphere composed largely of the dust of one of the most abrasive materials in the world. That, further, it shall receive its material with irregularities depending upon a thousand circumstances, and shall smooth these out and deliver the material properly to its place on the main bell. That it shall pass pieces of scrap iron up to several hundred pounds in weight, two or three feet in length, and of almost inconceivable roughness, without injury to itself, and without delay, and that finally the total height through which the material must pass in the performance of these operations shall be a minimum so that the coke shall be broken up as little as possible.

If in the scant twenty years which have elapsed since the mechanical top became widely introduced we have not achieved perfection in all these results it is perhaps nothing to cause surprise. In contemplating the long distance we have come from the vast amount of expensive labor, the derangements of the furnace due to frequent inability to keep it full and for the horrible results of the early attempts at mechanical filling, I think we have every reason to feel, if not satisfied, at least that we have made great headway, in one of the most difficult tasks of designing ever submitted to the engineer and metallurgist.

Hydrometallurgical Treatment of Michigan Copper Tailings

BY R. D. LEISK

The Calumet & Hecla Mining Company is developing a combination regrinding and leaching treatment for the accumulation of tailings below its great mill on Torch Lake. If successful the method will probably be applied to all the old mill dumps in the copper country which can be profitably worked. The process may also solve the problem of treating mine rock in which the copper is so finely divided and flaky that losses in ordinary milling treatment are excessive.

The cycle of treatment can easily be followed by reference to the accompanying diagram, Fig. 1, in which, however, no attempt is made to show detailed arrangement of plant or machinery. It should be first explained that the Calumet & Hecla at one time milled rock containing about 90 lb. of copper per ton, and that the milling practice of that day allowed millions of tons of tailings containing 13 lb. or more copper per ton to flow into Torch Lake. With the increased extraction made possible by modern milling methods these tailings have gradually developed into an asset.

The old tailings are to be taken from the bed of Torch Lake by a main dredge and conveyed by a pipe line supported on pontoons to a storage pond on the shore of the lake near the new plant. Here a set of suction pumps will elevate the pulp to a set of dewatering and classifying tanks. The slime from these tanks will pass over a set of Wilfley tables and the tailings from the tables will go to the leaching vats. The concentrates from the tables will of course go direct to the smeltery.

The sand from the classifying tanks will pass over dewatering screens onto a belt conveyor discharging into the storage bins of the regrinding plant which will contain 64 Hardinge mills. Pulp in the ratio of three

of water to one of solids will be fed to the mills at the rate of 35 tons per day for a 20-in. by 8-ft. mill. No classifier will be used on the discharge, as this would return coarse particles of copper for further grinding which is undesirable. The ground pulp will pass over Wilfley tables where free copper will be removed and the tailings discharged to the leaching plant.

The tailings which go into the leaching vats contain about one-half of the copper originally present in the sands. The chemistry of the leaching process depends upon a reaction well known in analytical chemistry, although its use for the recovery of copper on a commercial scale will be something new. The pulp contains too high a percentage of calcium carbonate for economical acid leaching. All copper which has gone through a milling treatment becomes covered with a slight film of

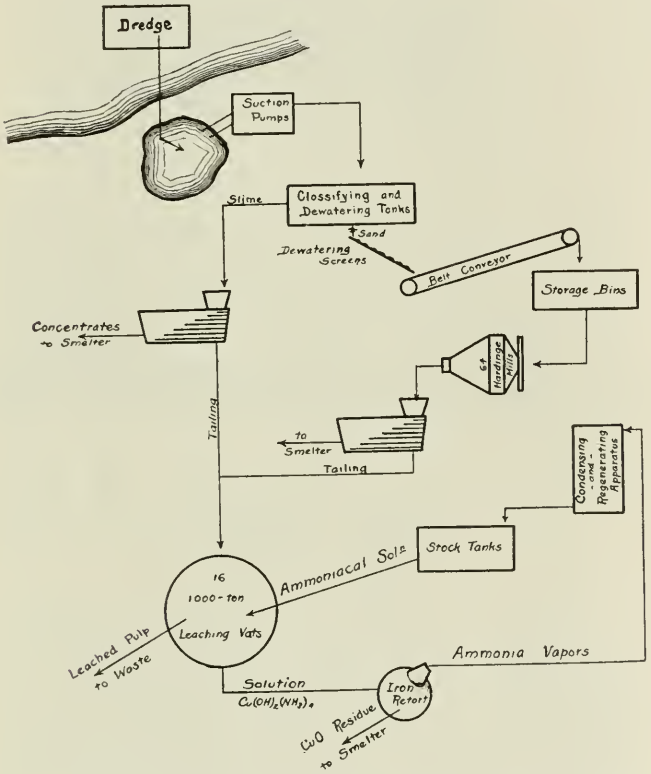

FIG. 1—DIAGRAM OF CALUMET AND HECLA COPPER LEACHING PROCESS

copper oxide which may be readily dissolved by ammonia in the presence of an ammonium salt such as ammonium carbonate.

$$CuO + 4NH_3.H.OH = Cu(OH)_2(NH_3)_4 + 3H_2O$$
(deep blue solution)

If a supply of oxygen is present in the solution, the film of oxide is at once renewed and the process is continuous until all the copper is consumed. The copper which is now in solution in the form of a double cuproammonium salt may be precipitated as oxide by distillation in ammonia-tight iron retorts. The ammonia vapor is recovered and regenerated, and the precipitated copper, in the form of oxide, may be mixed with grades from the stamp mill and charged to a reverberatory furnace. The process was first worked out in Germany on natural oxides and roasted ores, but the Calumet & Hecla Company is the first to apply it to native copper. Early experimenters precipitated the copper as sulphide by the use of H_2S, CaS, and BaS, but this is wasteful of ammonia and leaves the copper in an undesirable form for Michigan copper smelting equipment.

Plans for the leaching plant call for sixteen 1000-ton vats 54 ft. in diameter and 12 ft. deep. It is planned to complete the leaching treatment in a 91 to 96-hour cycle. In treating tailings containing 12 to 13 pounds of copper per ton it is expected to recover 5½ to 6 pounds on the tables and from 4½ to 5 pounds by leaching. The cost of leaching will be about 35 cents per ton and the recovery will be upwards of 70 per cent. The success of the process will depend upon how closely the working of the plant checks the results of the laboratory experiments, especially in the matter of losses of ammonia by volatilization. In the experimental work carried on by Mr. C. H. Benedict, the mill metallurgist, who has worked out the plans for the whole process, the working solution consisted of equal volumes of NH_4OH, specific gravity 0.93, and a saturated solution of $(NH_4)_2CO_3$. A more dilute solution will probably be used in the vats.

The plant is intended to run summer and winter. In winter the big dredge will be brought inshore and will dig in a small pond where the water can be warmed somewhat and kept in motion by the pumps. In summer the dredge, which has a greater capacity than the rest of the plant, will pump part of the sands into the excavation made the previous winter. The small pond in front of the second set of pumps is to give storage to tide over interruptions in the operation of the main dredge.

Work on the construction of the leaching plant has been halted temporarily, due to the general depression of the copper market, but the regrinding plant will be completed without delay. An interesting fact about the 40-hp motors which operate the Hardinge mills is that the electric power for them is developed by a low-pressure steam turbine driven by the exhaust steam from the stamps, which formerly was wasted.

Houghton, Mich.

Safety-First, First-Aid and Welfare Work of the Colorado Fuel and Iron Company

The safety and welfare of the employees of the Colorado Fuel and Iron Co. are administered through the medical and sociological departments, with headquarters at Pueblo, Colo., where the company's Minnequa steel works and Minnequa hospital are located. The Minnequa hospital has long held an enviable reputation among institutions of its kind. In the wake of its development and in harmony with the growth of a world-wide sentiment, have come those other evidences of attention to the human element suggested by the phrases "first aid," "safety first," and "welfare work."

Committees on Safety

The administration of the safety department in the Minnequa works is under the direction of Mr. F. E. Parks, assistant superintendent, and in the hands of a central committee and department committees comprising officials and employees. Department committees are charged with the inspection of conditions within their respective departments, observing and reporting dangerous conditions and recommending safeguards for the protection of workmen. Dangerous practices and careless habits of employees that might lead to preventable accidents also come under their observation and are made the subjects of reports. The reports are considered by the central committee, the superintendent of the department concerned and the reporting committee and plans are then laid for improvement in the dangerous practices or conditions. As a final safeguard the committeemen regularly inspect the provisions for safety to see that they are intact and in good repair.

The safety department was organized on its present basis in July, 1911. In the three succeeding years the

ompany spent over $20,000 in safety work. All sta-onary engines about the works have been equipped ith automatic speed-limiting devices. Overhead raveling cranes are provided with railings and guards. ubstantial platforms and railings have been erected long the trestles above receiving bins, and at over-ead valves in the works. Permanent stairways have een substituted for ladders at many places and rail-ngs and platforms provided at elevated points from hich a workman might fall during the discharge of is duties. Emery wheels are housed in adjustable teel guards designed at the works. Gears and motors re covered or surrounded by substantial iron-pipe ailings, and guards are placed about moving belts to revent accident in case of breaks. In some cases notors have been elevated so that the belts, properly uarded, run above the workmen's heads. In general, very precaution has been taken to prevent employees rom becoming accidentally entangled in moving ma-hinery.

The legend "Safety First" is before the workmen at ppropriate places, as shown in several of the accom-anying illustrations, being displayed with special rominence on a trestle in full view of all the men as hey pass over a viaduct to enter the works. The umbered brass check carried by every employee also ears the same words stamped on its face.

Physical Examination Required

In order to secure a class of employees fit for work n the plant and to avoid the employment of men who, hrough previous physical disqualification might be-ome a needless charge on the medical department, the ompany instituted in 1912 a system of examination or applicants. By this arrangement each applicant or employment is required to sign an application and ecord card and to pass a physical examination by a ompany surgeon. Table I shows the examination ecord. The examination is made at the Minnequa vorks dispensary without expense to the applicant. Boys under the age of 16 years and men over the age of 59 years or who are apparently under or over hose respective ages, are not accepted for employ-nent. Every employee is expected to be mentally and physically sound and fit for his work. An applicant is disqualified for employment if his examination re-veals any of the following physical disabilities:

"Loss of an eye, a hand or a foot, crippled, deafness, advanced tuberculosis in any form, epilepsy, fits or fainting spells of any character, active syphilis, running sores or any venereal disease, spinal affection heart disease, varicose veins, hernia, alcoholism, or any defect which would make it impossible for him to render regular and efficient service."

The diversity of races and nationalities represented among the employees adds to the problem of providing for their safety and welfare. Where men of only two or three nationalities are employed it is sometimes possible to post signs about the works, giving directions or cautions in several languages; but this is scarcely feasible where so many nationalities are represented. Table II gives a classification of 3689 employees of the Minnequa works, by races and departments as existing in August, 1914. The arrangement is in order of numerical predominance. Twenty-seven races are embraced. Americans predominate, comprising roughly one-third of the total; and for the most part they occupy the responsible positions. Austrians and Italians combined slightly exceed Americans in number and are employed mainly about the furnaces and in the mills.

Rescue Car for the Fuel Department

The fuel department, under the superintendence of Mr. E. H. Weitzel, maintains a rescue car for use at the company's coal mines. The car is equipped with first-aid cabinets, safety lamps, rescue helmets and various apparatus for use in case of coal-mine explosions. Training in first-aid and rescue work is given miners, who are granted certificates of proficiency on completion of a required course of instruction. In order to aid employees in passing state examinations for responsible positions about the mines a correspondence school was organized by company officials and instruction was given by mail and through night schools in charge of representatives of the local division engineers. As a result of this work 265 men took examinations in 1913 and practically all were successful in securing state certificates as fire bosses and mine foremen.

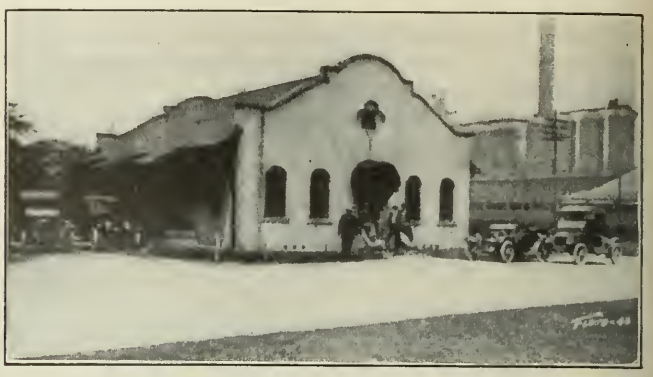

FIG. 2—STEEL WORKS DISPENSARY

Hospital and Dispensary Service

The proximity of the Minnequa hospital to the works, as shown in Fig. 1, and the location of the dispensary at the plant, Fig. 2, makes unnecessary the distribution of first-aid equipment throughout the various departments. The dispensary, under the direction of Dr. C. V. Marmaduke, affords medical treatment and handles minor surgical cases; gives vaccination to all employees without exception, and conducts an educational propaganda in prophylaxis. It is interesting to note that among the minor surgical cases, "foreign bodies in the eye" account for about 1000 each year, though the percentage of such accidents is

FIG. 3—SAFETY FIRST SIGNS ABOUT THE STEEL WORKS

claimed to be no greater at the Minnequa works than in other outdoor occupations.

The good effect of the safety work in the plant and of the required physical examination of applicants for employment is reflected in the dispensary report for the year ended July 1, 1914. Major injuries have been greatly reduced and the efforts to conserve health have shown commendable results that cannot be attributed to chance. In the matter of physical examination the records show that the percentage of rejections has fallen from 25 per cent during the twelve months following the adoption of the system to 15 per cent at the present time. This decline is accounted for by the general knowledge among possible applicants that the physical requirement for acceptance is held at a certain standard.

The Minnequa hospital affords treatment for sick and injured employees from the coal mines as well as from the steel works. The expenses and full railroad fare to and from the hospital are paid by this department. Employees who are helpless through permanent injury received in the company's service are kept at the hospital indefinitely, some having been

FIG. 4—SAFETY FIRST SIGNS ABOUT THE STEEL WORKS

there as long as 20 years. When space permits, the hospital is open to private cases on usual terms. This practice helps defray running expenses, aids in the maintenance of a competent staff and affords evidence to employes that they receive the same treatment as that accorded to patients who pay for the service. Even with this income, however, added to that received from the monthly charge on all employees, the company finds it necessary to meet an annual deficit for hospital maintenance.

Hospital Innovations

Under the direction of Dr. R. W. Corwin, chief surgeon for the company, the hospital has evolved from a small frame building containing 25 beds, in 1880, to the present magnificent institution with 216 beds. It is characterized by many innovations instituted by Dr. Corwin, that are not found at many other similar institutions. There are no stairways. The outer approach to the administration level, and inner connections between floors are by inclines on a grade of one foot in six, contributing to the ease with which healthy as well as sick persons can pass or be taken from one floor to another. This construction is illustrated in Fig. 6. Floors are covered with cork carpet; doors are of the noiseless swinging type and cannot be "slammed."

Every possible provision is made to eliminate dirt, odors and noise. Hospital signs bear the usual inscription "Safety First," and then admonish the reader to observe "Quiet Next." Special laboratories are provided for pathological and X-ray work. The operating room is specially interesting, having its floor, ceiling and three walls constructed of a continuous sheet of lead, while the fourth wall is formed of a large sheet of plate glass. The effect of the dull lead is to eliminate reflection of cross-lights, and it forms a surface

FIG. 5—SAFETY FIRST SIGNS ABOUT THE STEEL WORKS

that can be cleaned and sterilized by a jet of live steam.

For the education of employes in matters pertaining to health the hospital publishes regularly the *Sanitary and Sociological Bulletin.* This contains timely articles written in non-technical and popular form and is distributed free of charge. Illustrated lectures and entertainments are given periodically at the hospital chapel and residence.

Welfare Work

Special welfare work is conducted in the coal camps for the benefit of the miners and their families, under the direction of Rev. E. S. Gaddis, assisted by numerous

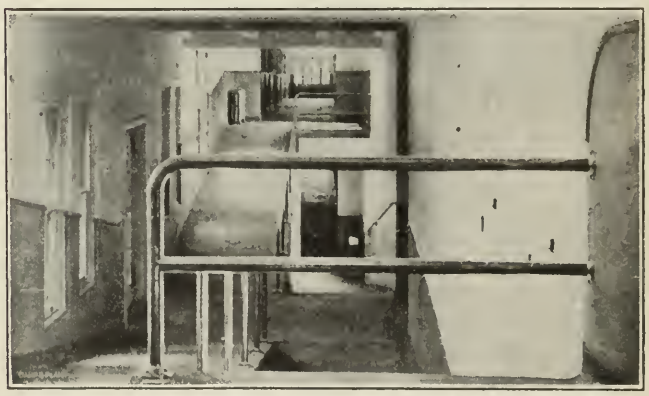

FIG. 6—VIEW OF INCLINE MINNEQUA HOSPITAL

local workers. Local company surgeons attend employes and their families, and maintain sanitary conditions in the camps. Education is under public control and regulation, as elsewhere in the state; but it receives attention from the sociological department, especially in the planning, lighting and ventilating of buildings and the activities of the pupils. First-aid exercises form a part of the instruction, even in the kindergarten. Reading rooms and social clubs are maintained for adults, and moving picture entertainments are given regularly.

The camps are also provided with churches, both Protestant and Catholic, in which services are held at regular intervals; and Bibles in several foreign languages as well as English are distributed free of charge.

During the recent labor troubles that occurred in the company's coal camps, saloons were closed by order of the State and remained closed during the greater part of 1914. From the opportunity thus afforded to observe the effects of enforced prohibition in the camps, the conclusion has been reached by company officials that the health, wealth and comfort of those communities were greatly enhanced. That this opinion was more widely shared is indicated by the fact that when the constitutional amendment for state-wide prohibition was before Colorado's voters last fall it was carried by large majorities in the strike districts where saloons had been arbitrarily closed for some time prior to election.

The Determination of Chromium and Vanadium in Steel

BY C. H. RICH AND G. C. WHITTAM

The oxidation of chromium by ammonium persulphate, as proposed by Walters,* has materially simplified the determination of that element.

Walters' method was proposed for the analysis of irons, usually of low chromium content. In adapting the method to the determination of chromium in steels, of 1 per cent or over, we have found that the oxidation of the chromium is incomplete in the volume of solution as prescribed by Walters. We have, therefore, modified the method to the extent of increasing the volume of solution at that point.

The combination of Walters' method for chromium and the J. Kent Smith method for vanadium, furnishes a very convenient method of procedure in the analysis of chrome-vanadium steels. Duplicate determinations of both chromium and vanadium may be carried through to completion in less than one hour and a single chromium determination may be completed in twenty minutes.

For those who prefer the internal indicator, the combination of the Walters and the Johnson methods, will be found convenient.

The critical points in the vanadium titration with the external indicator are the proper adjustment of conditions preparatory to the titration and the observance of a consistent end point, as subsequently to be described.

The Methods

CHROMIUM

One gram to 2 grams of the sample is transferred to a No. 4 lipless beaker and dissolved by heating with 40 cc to 60 cc dilute sulphuric acid (one part acid to five parts water). When in solution, 4 cc to 6 cc nitric acid (1.20 sp. gr.) is added and the solution is boiled until the iron is oxidized.

The solution is diluted to 170-180 cc and after the addition of 20 cc silver nitrate solution (1.33 grams per litre) is boiled during the addition of successive small portions of moist ammonium persulphate until the chromium is completely oxidized. The oxidation of the chromium is indicated in samples of low chromium content, by the precipitation of the manganese as dioxide, or, in samples of higher chromium, by the persistence of the pink tint of permanganic acid. The boiling is then continued a few minutes in order to decompose the excess of persulphate.

Two cubic centimeters, or slightly more if required, of strong hydrochloric acid is added and boiling is continued until the chlorine is completely expelled.

The solution is then cooled and diluted to 400 cc, a measured volume of the ferrous sulphate solution is added and the excess is titrated with the standard potassium permanganate solution. The percentage content of chromium is ascertained by appropriate calculation.

The ferrous sulphate solution is in close agreement with the permanganate solution, which is approximately $n/10$, standardized against sodium oxalate.

The relative value of the solutions is found by titration of 2 grams of plain carbon steel under conditions identical to those in the actual analysis.

VANADIUM

The slight excess of permanganate representing the end point of the chromium titration, is discharged by the necessary additions of the ferrous sulphate solution; one to two drops of permanganate solution is added and the resultant pink tint is discharged by careful additions of the $n/20$ ferrous sulphate.

A measured volume of the ferrous sulphate solution is then added and the excess is titrated with the standard potassium bichromate. The end-point in the titration is the first appearance of the momentary flush which spreads over the drop of ferricyanide upon the addition of the test drop.

Very small drops of the indicator are used, spaced upon the clean and smooth paraffined surface of a porcelain plate.

The test drop is dropped on the edge, rather than directly on top of the drop of ferricyanide. If there is difficulty in distinguishing the flush, the test drop is placed on the plate and is blown into the indicator by gentle blast through a piece of glass tubing: the flush is thereby rendered distinct.

The relative value of the bichromate and ferrous sulphate solutions is found by adding to the solution of 2 grams of plain carbon steel the same relative volume of the ferrous sulphate solution as is to be used in the actual analysis and titrating with the bichromate solution under the same conditions of control as in the analysis.

A more convenient method of procedure in either the chromium or the vanadium titrations, is to ascertain the relation of the respective ferrous sulphate and the permanganate and bichromate solutions, in acidified water solutions, and in the analysis account for blanks as determined in solutions of plain carbon steel. Blanks so obtained appear to be consistent and need be determined or verified, only at intervals.

Some results obtained are:

SYNTHETIC STEEL

Chromium		Vanadium	
Added	Found	Added	Found
3.88	3.85	0.25	0.23
3.10	3.07	0.21	0.20
4.97	4.96	0.25	0.255
4.97	4.92	0.25	0.242
4.97	4.97	0.25	0.242
4.97	4.96	0.125	0.127
4.97	4.96	0.146	0.153
6.22	6.17	0.125	0.127

The following vanadium results were obtained in synthetic steels of chromium content ranging from 3 per cent to 6 per cent but on which the chromium results were low owing to too concentrated solution in the oxidation of the chromium.

Vandium	
Taken	Found
0.25	0.23
0.21	0.20
0.50	0.49
0.25	0.248
0.25	0.242
0.125	0.127

4.13	4.15	0.21

Laboratory of the Alan Wood Iron & Steel Company, Conshohocken, Pa.

Removal of Carbon Bisulphide from Coal-Gas

In London *Engineering* of February 19 an interesting account is given of a recent lecture by Mr. E. V. EVANS before the Society of Chemical Industry on the way in which, after many years of varied experimenting, the South Metropolitan Gas Company has succeeded in getting rid of the obnoxious carbon bisulphide always present in coal-gas. "To Mr. Evans and to his chief, Dr. Charles Carpenter, the main credit is due for this triumph of engineering chemistry."

The amount of sulphur compounds, mainly carbon bisulphide (CS_2) remaining in coal-gas after the extraction of the sulphuretted hydrogen or hydrogen sulphide (H_2S) is only 0.02 per cent. That really is the chief trouble. At such high dilution only reactions of high velocity are likely to be effective.

Three methods appear available for the removal of the CS_2. The first rests on the absorption of both H_2S and CS_2 by lime or other alkaline earths and alkalis with the formation of a thiocarbonate. Unfortunately the lime absorbs also the carbon dioxide, which is a superfluous, though not an obnoxious, constituent of the gas, and prohibitive quantities of lime would be needed for this purpose. If not removed, however, the CO_2 decomposes the thiocarbonate; any oxygen present has the same effect, and attempts to regenerate the decomposed mass *in situ* have so far failed. The "athion" process, now on trial at Heidelberg, is open to the same objection that the carbon dioxide has first to be removed; the absorbent used there is alkaline cellulose. Absorption by solids is always slow, moreover; but liquid ammonia has not answered either; thus this first method is not promising.

The second method relies on the absorption of the CS_2 by amino compounds (aniline, toluidine, etc.) in the presence of a catalyst with the formation of thiocarbanilides, which form the starting point of the manufacture of artificial indigo by Sandmeyer's reaction. The products are volatile, however, and the cost of washing the gas with weak acids or oils to bind the amino componnds would be high.

The third method, which has now proved successful, is based on the observations by Vernon Harcourt and others that most of the sulphur compounds in coal-gas are decomposed and converted into hydrogen sulphide, H_2S (which is subsequently absorbed by iron oxide), when the gas is heated to 500 deg. C. Mr. Evans took this line of research up in 1908. He found that CS_2 was not decomposed when carried by a current of nitrogen, but that the reaction did take place, according to $CS_2 + 2H_2 = 2H_2S + C$, and was irreversible, moreover, when hydrogen or coal-gas acted as carrier for small percentages of carbon bisulphide; the presence of water vapor did not disturb the reaction, which, it is noteworthy, depends upon the action of hydrogen, not of steam. The presence of certain metallic catalysts, of large porosity (finely divided so as to offer large surface) accelerated this reaction; the carbon liberated by the reaction was deposited in the pores of the catalysts, but could be burned out again *in situ*.

Iron proved the most active catalyst available at low cost; the decomposition temperature was 450 deg. to 500 deg.; for the regeneration (by combustion or aeration) of the catalyst, the iron had to be heated to 450 deg. for several weeks; iron pipes answered as containers for the catalyst. Having ascertained the suitable volume and weight ratios, and found that 80 per cent of the CS_2 could be eliminated by the new process without deteriorating by the heating the quality of the coal gas, Mr. Evans had an iron retort made to deal with 50,000 cu. ft. (instead of 10 cu. ft.) per hour. The jump was too great. In spite of the interposition of a tubular heat-interchanger, the enormous volume of gas cooled the catalyst so much that hardly any decomposition took place, even when the retort was red-hot outside, and when the regeneration of the catalyst was tried a hole was burned in the retort.

Attempts were then made with porous clay impregnated with metallic solutions. In that condition iron

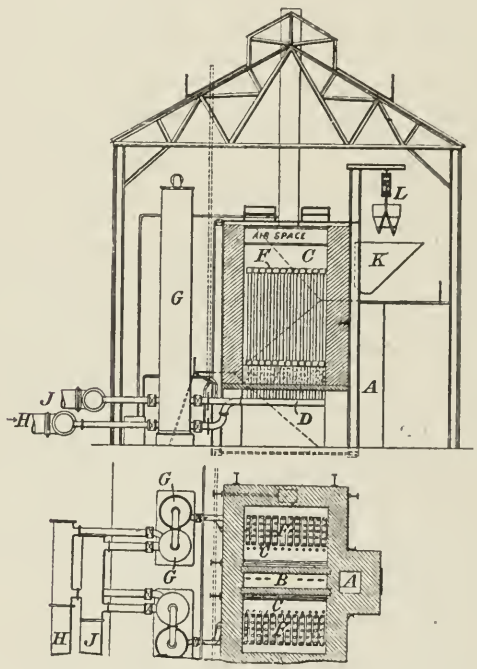

FIG. 1—PLANT FOR REMOVAL OF CARBON BISULPHIDE FROM COAL GAS

oxide was not active enough; nickel (reduced by hydrogen from the chloride) answered, but a higher temperature (600 deg.) seemed to be required for the reaction. That was undesirable, lest the coal-gas should be impoverished, and the deposition of carbon in the pores proved troublesome.

After a great deal of experimenting, in apparatus capable of dealing with 2000 cu. ft. of gas per hour, on the preheating of the gas, the amount, porosity, density and specific heat of the catalyst, the exposed surfaces of the catalysts and their containers and other features, a plant for 2,000,000 cu. ft. of gas per day was erected in 1911, and this was followed by a plant of five times that capacity (10,000,000 cu. ft. per day) in 1913. In these plants the gas is preheated by passing through 2-in. horizontal tubes before entering the four vertical reaction tubes, 6 in. in diameter, connected in parallel, the whole set being placed within the heating chamber. Such a unit dealt with 5000 cu. ft. of gas per hour, and in large plants a proportionate number of units were installed.

When Mr. Evans delivered his lecture the 1913 plant

had been in constant operation for almost two years, and, on an average, the percentage of sulphur compounds has been reduced to 2 per cent of the amount before treatment, that is, from 35 grains per 100 cu. ft. to 8 or 7 grains. In other respects the treatment makes little difference. The candle power and the thermal value are practically unchanged. There is a slight rise in methane (from 26.85 to 27.26). A little ammonia also results from the treatment. This is an advantageous feature, inasmuch as the ammonia keeps the iron oxide (wanted for absorbing the H_2S formed by the reaction) alkaline.

The catalytic material is a mixture of finely divided nickel (reduced from the chloride) and of a small quantity of nickel sulphide; the latter amount depends upon the ratio of H_2S to H in the original gas. Most of the sulphuretted hydrogen of the crude gas has to be removed before the treatment, otherwise carbon oxysulphide (COS) is formed by the interaction of the CS_2 and the CO in contact with the hot catalyst, and the presence of this undesirable COS becomes perceptible when the crude gas contains more than 100 grains of H_2S per 100 cu. ft. The above-mentioned increase in the methane percentage would be greater if the reaction were conducted under different conditions; it is partly the presence of sulphur which keeps it so low in the process under notice, because sulphur acts as a poison as regards methane production in the presence of nickel. It is interesting, as Dr. H. G. Colman emphasized during the discussion, that nickel is poisoned as a catalyst by sulphur at 250 deg., but is so no longer at 450 deg. The contact between nickel and carbon monoxide might be thought to lead to the formation of nickel carbonyl; the Mond nickel reduction process is based upon the fact that nickel and carbon monoxide form a volatile compound at about 100 deg. C., which is decomposed with deposition of metallic nickel above 200 deg. C. The presence of this poisonous nickel carbonyl in coal-gas, from which nickel might afterward be deposited, would be most objectionable. No trace of nickel has, however, ever been detected in the gas treated by the Evans process, even when the working temperature had been lowered to 250 deg. C.; yet, to make sure of its exclusion, contact between the gas and the nickel is not allowed to take place at a temperature below 300 deg.

The latest and largest of these installations is the plant put up at East Greenwich in the early part of 1914. The capacity of the plant is 15,000,000 cu. ft. of gas per day; it is divided into five units, each of 3,000,000 cu. ft. The 2-in. preheating pipes have, at Greenwich, been replaced by heat-interchangers erected outside the furnace setting. The general arrangements are illustrated in Fig. 1. Each unit consists of a central producer *A* surmounted by a combustion chamber *B;* on both sides of *B* are heating chambers, in which a temperature of from 420 deg. to 440 deg. C. is maintained about the reaction tubes *F* containing the catalyst. The gas entering through the pipes *H* is preheated to a small extent in *C;* the chief preheating takes place in the heat-interchangers *G*, in which the gas flows in the opposite direction to that requiring treatment; *D* is the collector tube and *J* the pipe carrying off the treated gas; *K* indicates the hopper and *L* the coke-handling plant. When the catalyst is to be revived, the temperature in the heating chamber is lowered and air is pumped through the reaction tubes at a definite rate, this process requires about a week, during the first four days of which all the oxygen of the air is taken up by the carbon deposited in the catalyst and burned to carbon dioxide. When oxygen appears in the effluent gas the temperature in *C* is raised to 430 deg. C and is kept at that height until the evolution of CO_2 has ceased. The aeration period is then complete, and before starting the decomposition the air left in the pipe system is swept out with waste combustion gases; similarly, the gas is swept out by combustion gases when preparing for aeration. The catalyst remains active in its tubes for thirty or thirty-five days, then the efficiency falls off and is restored by the aeration process just described. No deterioration of the nickel has so far been noticed after two years' working.

The capital outlay for plant per million cubic feet of gas per days was estimated by Mr. Evans to be about £1,500 ($7,500) and the working cost at 0.3d. (0.6 cent) per 1000 cu. ft. of gas, this latter figure including interest on capital, depreciation, repair and maintenance. This expenditure is not prohibitive. As has already been stated, some sulphur—7 or 8 grains per 100 cu. ft. —is still left in the gas. This sulphur is mainly present as thiophen, but there are other organic sulphur compounds not yet identified. Various methods have been tried to remove them, so far without real success. In Sweden the carbon bisulphide itself has been eliminated by washing the gas with alcohol, which absorbs the thiophen as well as the CS_2. This process is to be tried in England. The advantage of the alcohol treatment, as well as of the Evans process, is that the gas can be treated as such without previous removal of the carbon dioxide.

Standard Boiler Specifications

One of the most notable achievements of any engineering society is that of the American Society of Mechanical Engineers in connection with standard boiler specifications. This society some four years ago appointed a committee of seven prominent engineers to "formulate standard specifications for boilers and other pressure vessels and for care of same in service," in order to put an end to the increasing number of boiler explosions in this country and the resultant fearful toll of death and destruction.

The members of this Boiler Code Committee upon their appointment immediately set to work to draw up according to their best judgment a set of rules which would specify boilers of such high type that boiler explosions would be reduced to a minimum.

Each member gave unstintingly of his time and money to make this formulation of rules a success and, after three years of the most effective research work, a preliminary draft of rules was drawn up and sent confidentially to professors of engineering in prominent technical schools of this country, superintendents of inspection, departments of insurance companies, chief inspectors in charge of United States, State and municipal boiler inspection departments, prominent engineers known to be interested in the construction and safe operation of steam boilers, prominent manufacturers of steam boilers and editors of engineering journals—some two thousand persons. Each one was invited to read over this report, criticise the same and make any suggestions if they so desired.

An Advisory Committee was appointed in December, 1914, and from that time until the middle of February, they worked unceasingly, until the report was finally completed.

This report was presented to the Council of the American Society of Mechanical Engineers, February 13, 1915, and the Council voted unanimously to accept the report, and further than that, they voted to make the Boiler Code Committee and its Advisory Committee permanent under the name of the Boiler Code Committee of the American Society of Mechanical Engineers.

Fixation of Atmospheric Nitrogen

The fixation of atmospheric nitrogen was the subject two papers presented on the evening of March 12, 15, in a joint meeting of the American Institute of ectrical Engineers and the New York Section of the nerican Electrochemical Society. President Paul M. ncoln of the American Institute of Electrical Engi- ers presided.

General Review of Nitrogen Fixation Processes

The first paper was presented by Mr. **Leland L. mmers**, of L. L. Summers & Company, Chicago, Ill., d gave a very good résumé of the whole subject. The per is printed in full in the March issue of the *oceedings* of the American Institute of Electrical ngineers (p. 337 to 371).

The three fundamental products formed by nitrogen e, first, its union with oxygen to form nitrates XNO_3 d nitrites XNO_2; second, its union with carbon to rm cyanogen C_2N_2 and producing cyanides XCN and anamides XCN_2; third, its union with hydrogen, rming ammonia, NH_3. The present industrial situa- n with respect to these three groups of nitrogen prod- ts is reviewed. The available nitrogen in the various mpounds determines the price, at least as far as their e in the fertilizing field is concerned, and for a num- r of years it has been assumed that the selling price combined nitrogen would be from 12 to 13 cents a und.

The author gives a review of the different fixation ocesses which have been proposed, and then discusses some length the theoretical limitations of arc proc- ses on the basis of the thermodyamical theory of the uilibrium between N_2, O_2 and NO and the reaction locity of the formation and dissociation of NO—if e reaction is a purely thermal one. "We may assume at up to the present the [arc] processes in commercial e are limited strictly by the thermodynamic equili- ium of the Van't Hoff equation. As the volume of ses when working with low concentrations of NO are nsiderable, the radiation and convection losses as well the transfer of sensible and latent heat from the arc the gases lower very materially the temperature of e arcs, and the yields therefore indicate an average orking temperature of 2200 deg. Cent. to 2500 deg. ent. or concentrations of 1.5 to 2 per cent NO when orking with air. These theoretical limitations of the rect process of forming NO have, therefore, led to any efforts to dissociate the nitrogen molecule by her means."

The common elements exhibiting the most pro- ounced tendency to combine with nitrogen (in the sence of oxygen) are Ca, Mg, Al, B and the carbides a large number of metals. The author gives the eoretical reasons why for such processes the actions nd reactions must not only be subject to accurate tem- erature regulation but the partial pressures must be ntrolled and it is probable that definite zones of re- tion must be maintained.

Mr. Summers then takes up the description of those rocesses which have been commercially applied. Of rc processes for nitric acid production there are three: irkeland-Eyde, Schoenherr and Pauling (all of which ave been described and illustrated formerly in this ournal).

The latest Birkeland-Eyde furnaces are of 3000 kw apacity and give concentrations of about 2 per cent NO and a yield of 580 to 600 kg of nitric acid per w-year, or 65 to 70 grams of nitric acid per kw-hour.

The largest Schoenherr furnaces are of 800 kw apacity and maintain an arc 23 ft. (7 meters) long. hey give an NO concentration of 2.25 per cent and a yield of 550 to 575 kg per kw-year, or 65 grams per kw-hour.

For the Pauling process the percentage of NO obtained is 1.25 to 1.5 per cent in the 400-kw furnace, while the yields are 525 to 540 kg per kw-year, or 60 grams per kw-hour.

In all these processes where the arc is distorted the power factor is about 70 per cent, being about 5 per cent lower in the Schoenherr type.

All of the above concentration figures indicate that the maximum temperature of the arc is not utilized, but is very considerably reduced by the large amount of air admitted. If the temperature of the arc is raised by admitting less air there is a heavier decomposition of the products and all products are heated to a higher temperature with a corresponding loss, the net result being a lower yield per kw-hour. As the yield per kw-hour is of fundamental importance, adjustments are governed accordingly. The concentration of NO effects directly the apparatus for recovering the products, such as the absorbing towers, and the lower the concentration of NO the greater the losses from heating the inert gases. The furnace efficiency will largely be determined by this factor. A numerical example is figured out.

The author gives brief notes on Hausser's process utilizing coke oven gases by means of an explosion bomb, and points out that all of the above nitric acid processes utilize the reaction

$$2NO + O_2 = 2NO_2$$

which is an exorthermic one for the formation of the peroxide, and if the temperatures are controlled, side reactions can be prevented and equilibrium can be maintained with only a small percentage of NO remaining. The gases after leaving the furnaces are usually carried through waste heat boilers where 50 to 60 per cent of the heat is utilized for steam production. They are then cooled in aluminium pipe coolers and allowed to enter a gas holder where time is given to form the peroxide. The products then enter counter-current absorption towers where the reaction with water forms

$$2NO_2 + H_2O = HNO_3 + HNO_2$$

the nitrous acid HNO_2 is further oxidized and utilized to form HNO_3 in contact with the excess oxygen in the gases and with the absorbing water. The final recovery is usually made by circulating the gases through two towers of weak alkaline solution, such as sodium carbonate and this is converted into sodium nitrate and into sodium nitrite, and recovered by evaporation, the final products are a combined nitrate-nitrite of sodium. A normal circulation over three absorbing towers gives an acid of about 30 per cent concentration, but this can be increased to 45 or 50 per cent by recirculating over the first tower. Further concentrations are usually made by evaporation. All of these processes are simplified by increased concentrations of NO in the initial reaction. About 2 to 3 per cent of the original NO is discharged in the waste gases from the absorbing towers. It will be noted that one great advantage of these processes is that they require the handling of only air, gas and water up to the time the nitric acid is formed in the absorbing towers, so that the simplest handling devices suffice, and the labor is a minimum, also no chemicals are required until the final washing with the alkaline solution in the absorbing towers, and this may be a cheap solution such as lime water if conditions make it desirable.

The author then gives brief descriptions of the cyanamid process, the Serpek aluminium nitride process and the Haber synthetic ammonia process, and finally discusses the economics of nitrogen fixation.

Nitrogen is only one of the three important ingre-

dients of fertilizers, the other two being phosphorus and potassium.

"Prices of Nitrogen.—In general the price of combined nitrogen is fixed by the price of Chile nitrate. If this sells for 2 cents per pound and contains 15 per cent N, the price per pound of N is 13.2 cents and this in turn would make the price of ammonia sulphate having 21 per cent of nitrogen 2.7 cents per pound. These have been current prices. In considering the production of nitrogen products it would seem that while these prices control nitrogen for the fertilizer industry it would be desirable to produce if possible products which are manufactured from these crude products, and thus avoid competition with the natural products direct. Nitric acid of commerce is manufactured from soda nitrate by treatment with sulphuric acid, about 72 per cent of the sodium nitrate being nitric acid. As the by-products of this operation only partially pay the costs, the manufacturing costs leave the nitric acid with a value of 50 per cent over the value as nitrate. Hence chemical works could afford to produce nitric acid when they could not afford to add a manufacturing cost to produce a fertilizer from the nitric acid and then sell it in competition with the crude Chile nitrate.

"A large portion of the phosphate rock of this country is treated with sulphuric acid to form the so-called super phosphates. If nitric acid is used in place of sulphuric acid the super phosphate can be produced at the same time as a fertilizer of lime nitrate, or if preferred a high concentration of phosphoric acid can be produced from lower grade phosphate rock. Industries of this kind promise more favorable results commercially than does the direct production of fertilizer. If low grade products are manufactured at close prices a very large volume of business is a necessity and works of this character and magnitude are more apt to be a result of successful development rather than an initial venture in a field beset with uncertainties as to the profits and the chances of a development of other processes reducing these if they are problematical.

"Costs of Making Products.—Let us consider more in detail some of the costs. We may assume approximately that the labor and repairs in furnace room and absorbing tower will cost $10 per ton of nitric acid and if nitric acid is selling for $60 per ton, we have a margin for power cost, interest, general expense, etc., of $50, and if we produce 500 kg of acid per kw-year it will require 2 kw-year per metric ton or $25 per kw-year, and we must absorb all interest charges and general expense in this. If the yield can be made 550 kg per kw-year and we can sell for $60 per short ton, we will require 1.8 kw-year, or $28 per kw-year. We must assume that the product does not have to be packed for shipment and that there are no selling costs involved, and we must figure on an output so that our units may be large enough to bring the investment in plant down to $80 per ton of acid so the annual charge may be $8 or net $20 per kw-year, and if $5 are allowed for general expense the best we can do will be about $15 per kw-year.

"We see it would be hopeless to attempt to put this acid into a product to compete with the fertilizer prices, for they are some 50 per cent lower in selling price, and it will involve a cost for some raw material to mix with the acid, the cost of manufacture and a packing and shipping charge. We must then abandon any idea of making fertilizer from nitric acid prepared by the direct oxidation of atmospheric nitrogen in the electric arc until such time as we can improve the very low efficiency due to the thermodynamic limitations of the reaction. We can only hope to utilize this process in the manufacture of nitric acid coupled with some other product which will procure for it a higher price. There is for example a limited demand for the nitrite of sodium $NaNO_2$ used in the dye industry and this is manufactured by reducing nitric acid with molten lead thereby adding another manufacturing operation to the acid cost. This nitrite may be cheaply made by taking a mixture of NO and NO_2 such as we would have in parts of the system and passing it into water or sodium hydroxide,thus

$$NO_2 + NO + H_2O = 2\,HNO_2$$

or

$$4\,NO + 2\,NaOH = N_2O + 2\,NaNO_2 + H_2O$$

and this process would produce a product selling for 4 to 5 cents per pound. We must remember, however, that the price of nitric acid is not a fixture and that a cheap combined nitrogen fertilizer will cut the price of sodium nitrate and hence the price of nitric acid. We are confronted then with the fact that all processes will be affected by the success of any one process that is a large enough success to affect the market conditions of combined nitrogen and upset the ruling prices in the fertilizer industry. It is useless to look only to cheap power as a solution of this problem as the real solution is in the improvement of processes.

"Let us roughly compare the power requirements of the processes as we have outlined them and we find

Direct oxidizing of atmospheric nitrogen 5 per cent. efficiency, yield at 550 kg. per kw-year, requires per kg. of N	65 kw-hr.
Cyanamide process 66 per cent efficiency in carbide 1 per cent loss in heating to combine with N., requires per kg. of N. Also preparation of N.	16.6 "
Aluminum nitride using coal to heat products to temperature of reaction requires per kg. of N	12 "
Catalytic method of combining N and H to form ammonia, requires per kg. of N. Also preparation N and H, refrigeration, and compression to 200 atmospheres.	1.5 "

"The general tendency abroad in figuring the cost of water power is to give only the operating costs and from this one sees costs of producing power figured at from 50 cents to $1 per kw-year and in using these figures erroneous ideas have been widely circulated. In this country it has been standard practice to consider the investment in the power plant, that is, the cost of the development and the property, as fixing very largely the cost of producing the power. It is quite common to have labor and supplies cost not more than $1 per kw-year, but this would not be considered as representing the cost of the power. Where a chemical industry owns the hydroelectric power plant as well as the chemical works, the foreign practice is inclined to consider the investment as a whole and apportion the costs of operation to the various departments, while interest on the capital is charged to the profits. The costs of producing power are therefore uniformly much lower than we are accustomed to figure on. There are many plants in operation in the chemical industries abroad whose real costs of producing power are no lower than many of the more favored locations in this country.

"Off-Peak Loads.—One of the chief interests in the chemical utilization of electrical energy is centered in the possibilities of off-peak or off-season loads, as American plants generally have a certain proportion of power which can be disposed of to better advantage than selling the entire output as low priced power to chemical industries. This off-peak power is difficult to utilize in furnace work, where the cooling of the furnace and its charge is an important factor, both from the standpoint of cost and of output, and again adjustments may be so disturbed from an interrupted output as to be absolutely impracticable. One of the possible solutions for off-peak utilization appears to be in the adoption of some system where fuel is also utilized and the

radiation losses are not excessive under conditions of banked fire when the electric portion of the heat energy is not in use. Some of these combination processes may promise a solution of the off-peak load situation more attractive than the straight electric furnace, which is difficult to cool down entirely without unduly affecting the conditions. In all plants the volume of output is the determining factor in absorbing the general overhead charges, and any intermittance must diminish output with its accompanying disadvantages.

"If the furnace could be operated on the off-season load and its product stored, and the chemical works utilizing this product could operate on a normal schedule, this would form one solution; or another would be if by chance the off-season power were available at the time the greatest demands were to be met, such as preparing a fertilizer product at the season of fall rains for the early spring delivery. All of these plans, however suggest the necessity of operating at least a portion of the plant continuously in order to meet fixed charges and preserve an operating organization. If the chemical works requires a moderate amount of power for its processes in year around operation and only its surplus for manufacturing its crude material at the off season peak it promises the greatest possibilities."

Mr. Summers concluded that the future of nitrogen fixation is alluring and promises many developments along lines other than those considered, but already the market has felt the effects of these various processes and instead of nitrogen being figured at 13 cents per pound, it is confidently predicted it will very shortly find its level at a selling price of about 8 cents, making a cost of production of 5 to 6 cents per pound and thus reducing sodium nitrate to about 1.33 cents per pound, or approximately $30 per long ton, and the lower grade mines will feel this and be forced to curtail.

The Cyanamid Process

The second paper of the evening was presented by Mr. **Frank S. Washburn**, president of the American Cyanamid Company, on the cyanamid process. As this paper is to be called up for discussion at the general meeting of the American Electrochemical Society in Atlantic City in April, we reserve a full report of the paper for our next issue and will give here a short abstract only.

In his paper Mr. Washburn pointed out that while the industries of the fixation of atmospheric nitrogen are only ten years old, they have reached a great commercial importance. The annual productive capacity of the existing plants employing the "arc" and "cyanamid" processes is between 90,000 and 100,000 net tons of fixed nitrogen, which, at the normal average value of the product at the factory door, represents $25,000,000. This is divided in the ratio of two-thirds to "cyanamid" and one-third to the "arc" process. The American Cyanamid Company's factory at Niagara Falls, Canada, has alone a capacity in fixed nitrogen approximately half as great as the total world's installed capacity by the "arc" processes.

Mr. Washburn then took up the economic aspects of nitrogen fixation on the North American Continent. Nitrogen is used largely for three purposes: For crop fertilizer, for the production of nitric acid and its derivatives and for the production of ammonia. Nitric acid is relatively a small business, as great industries go, The fertilizer industry, on the other hand, is of immense importance.

Mr. Washburn pointed out the necessity of increasing crop yields without additional labor—that is, by the use of artificial fertilizers. European yields per acre cultivated are 50 to 100 per cent greater than American yields. The use of fertilizers in Europe per acre cultivated is enormously greater than in America. The average increase in yield in Germany for the past twenty years has been approximately 60 per cent, in the United States 20 per cent. Abroad this increase is attributed to intensive farming, better selection of seed, the rotation of crops, and, to the extent of 50 per cent to 70 per cent of the increase, to the use of commercial fertilizers.

Mr. Washburn emphasized that if the American farmer is to use more fertilizer nothing is more important than to place at his disposal a high-grade chemical salt containing nitrogen and phosphorus, well balanced and in large percentages, and possessing in a high degree the many requisites of a good fertilizer, such as being non-hygroscopic, non-toxic, finely granular in form, non-leachable in the soil and readily convertible by nature's forces into the organism of the plant.

The author gave considerable data on comparative costs of the various atmospheric nitrogen fixation processes and their prospects in the United States. He thinks that the arc processes will be restricted to nitric acid field and it will not pay them to go into the nitrate business. On the other hand, the ammonia processes may go into the nitric acid field. The author's argument tended toward the conclusion that the cyanamid process seems destined to play the leading role in the fixation of atmospheric nitrogen in the United States. Unique in air nitrogen fertilizer processes is the direct and valuable application of the raw product cyanamid, as is proven by the fact that fully 80 per cent of the entire annual product of normally $15,000,000 value is sold as the raw product. But there is also a long list of promising derivatives, ammonia, urea, cyanides and argon (used in the lamp industry).

Discussion

The discussion was opened by Dr. J. W. Richards, who reviewed the great progress made in recent years, but emphasized the "wonderful inefficiency" from the thermal and energy standpoint of all processes for the fixation of atmospheric nitrogen. The thermal efficiency of the nitric-acid arc process is only about 1.4 per cent, while the cyanamid process fixes about twice as much atmospheric nitrogen per kw-hour. There is a wide margin for improvement.

Mr. J. L. R. Hayden, in a communicated discussion, said that a series of experiments in Dr. Steinmetz's laboratory with arcs of different temperatures (produced by using different electrode materials, iron, titanium, carbon and copper) showed no direct relations of the NO concentrations to the arc temperature. He considers that the essential phenomenon in the arc is the dissociation of the oxygen and nitrogen molecules into N atoms and O atoms, which pass out of the arc and combine with each other according to the probability law.

Mr. D. B. Rushmore emphasized that our civilization is absolutely founded on the layer of from 4 to 6 in. of soil on the surface of this earth, and the conservation of this layer is an absolute necessity, and we have still very much to learn on fertilizing. He suggested the possibilities of development of water powers in agricultural districts and asked as to the effect of the electric field in arc processes.

Dr. C. A. Doremus referred to a treatise published in 1802 by Felix Pascalis, in which he referred to the possibility of manufacture of nitric acid from nitrogen of the air according to the expectations of Citizen Guyton. It has required a world conflagration to make us in this country appreciate our possibilities.

Mr. F. V. Henshaw asked as to the requirements of geographical location of nitrogen fixation plants.

Mr. Washburn replied that for pure cyanamide factories interior water power plants serving adjoining agricultural districts would do, but for the manufacture of ammonia-phosphate fertilizers cheap water transportation is as necessary as cheap water power. He said, however, that the beef-packing business was successful in spite of very large shipping bills, and a great nitrogen industry will be also able to face successfully similar handicaps. But this means manufacturing at one point on the largest scale.

Mr. Summers, in closing, said in reply to Mr. Rushmore's last question that at the high temperature of arc processes dissociation is so active that though there was an electrical effect it would be overcome and the final effect is purely thermal. Ozone, on the other hand, is produced at low temperature.

Chemical Reactions at Low Pressures

On the evening of Friday, March 5, in a meeting of the New York Section of the American Chemical Society, held in the Chemists' Club in New York City, the Nichols gold medal was presented to Dr. IRVING LANGMUIR, of the Research Laboratory of the General Electric Company, Schenectady, N. Y., for his research work on chemical reactions at low pressures.

IRVING LANGMUIR

The presentation of the medal to Dr. Langmuir was made by the chairman of the Section, Professor Allen Rogers, in a felicitous little speech. Dr. Langmuir, in expressing his thanks, modestly laid great stress on the help and co-operation he had had in his research from others. Dr. Langmuir then presented a long formal paper on "Chemical Reactions at Low Pressures," of which we herewith give a brief abstract.

In the course of the author's investigations into the causes of the blackening of tungsten lamps the effects produced by the introduction of low pressures of various gases were studied in considerable detail. It had been previously known that the vacuum in a lighted tungsten lamp normally improves during the life of the lamp, but it was thought that this removal of the residual gases was brought about by electrical discharges in much the same way as that commonly observed in Geissler and Roentgen ray tubes. These experiments have shown, however, that a highly heated tungsten filament will cause the disappearance or clean-up of nearly any gas introduced into the bulb at low pressure, and that this action, in the great majority of cases, is purely chemical in nature.

The experimental methods that were employed in these investigations are relatively simple. A bulb containing one or more short filaments, usually the tungsten, was sealed to an apparatus consisting essentially of a mercury Gaede pump, a sensitive McLeod gage for reading the pressure, and an apparatus for introducing small quantities of various gases into the system and for analyzing the gas residues obtained in the course of the experiments.

By means of the pump the pressure in the system could be lowered to 2/100000 of a mm of mercury. The McLeod gage gave a reading of 1 mm on the scale for a pressure of seven millionths of a millimeter of mercury. By means of the apparatus for analyzing gas, a quantitative analysis of a single cubic millimeter (at atmospheric pressure) of gas could be carried out, determining the following constitutents: Hydrogen, oxygen, carbon dioxide, carbon monoxide, nitrogen and the inert gases.

In a typical experiment, after having thoroughly exhausted the whole apparatus, a small quantity, usually 5-20 cu. mm of gas, is introduced and the filament is electrically heated to a definite temperature, while readings of the pressure are taken at regular intervals (usually one minute). By plotting the pressure readings against the time, a curve is obtained which clearly shows how the rate of clean-up varies with the pressure.

In this way the author studied the clean-up phenomena with many different gases and several different kinds of filaments. Most of the work was done with tungsten filaments, but in order to get a broader outlook over the field of low pressure reactions, filaments of carbon, molybdenum, platinum, iron, palladium and other metals were also tried. The principal gases studied were oxygen, nitrogen, hydrogen, carbon monoxide and dioxide, chlorine, bromine, iodine, methane, cyanogen, hydrochloric acid, argon, phosphine and the vapors of many substances, such as mercury, phosphorous, phosphorus pentoxide, sulphur, etc.

With each of these gases, conditions could be found under which a heated tungsten filament will cause the clean-up of the gas. The curves obtained in the course of the experiments furnished very complete data for a study of the kinetics of the reactions involved.

Dr. Langmuir points out that the study of gas reactions affords the best means of studying the reaction mechanism, and that by the use of extremely low pressures the experimental conditions are enormously simplified. The reaction velocity is then much more intimately related to the behavior of the individual molecule than it is at higher pressures. The reaction velocity becomes a matter of statistics. The question is: Out of all the gas molecules which strike the surface of the heated filament, what fraction will enter into reaction with it?

Dr. Langmuir's researches related to reactions between gases and heated filaments, that is, heterogeneous reactions involving a solid and a gaseous phase. Comparatively little work has been done in the past on heterogeneous reactions.

It was at first thought that the law of mass action could be applied to heterogeneous reactions just as to homogeneous reactions. Experiments soon showed, however, that other factors than purely chemical ones usually determined the velocity of these reactions. Noyes and Whitney (*Zeit. Physik. Chem.*, vol. 23, p. 689, 1897) studied the rate of solution of solid substances in liquids and concluded that the velocity was dependent entirely on the rate at which the dissolved substances could diffuse out through the thin layer of liquid next

to the solid. Stirring the liquid had the effect of thinning this layer and so increased the rate.

Nernst extended this idea and suggested that the velocity of heterogeneous reactions in general was limited by the rate of diffusion of the reacting substances through a "diffusion layer," which he considered, under ordinary circumstances, to be of constant thickness. Thus he reasoned that the velocity of these reactions in practically all cases should be proportional to the concentration of the reacting substances. In other words, the reactions should follow the laws of monomolecular reactions. Nernst pointed out, however, that it was wrong to draw conclusions as to the mechanism of heterogeneous reactions from velocity measurements.

Dr. Colin G. Fink (Dissertation Leipzig 1907: see also Bodenstein and Fink, *Zeit. Phys. Chem.*, vol. 60, p. 1, 1907), as a result of his study of the kinetics of the sulfur trioxide contact process, developed a theory of the mechanism which marked a new step in our conceptions of the mechanism of heterogeneous reactions. Bodenstein and Fink (*Zeit. Phys. Chem.*, 60, 46, 1907) successfully applied this theory to a large number of other catalytic reactions.

This theory differs essentially from Nernst's in that the rate of diffusion of the reacting bodies through an *adsorbed film* of *variable thickness*. Thus, in the case of the reaction $2\ SO_2 + O_2 = 2\ SO_3$ in contact with platinum there is present on the platinum an adsorbed layer of SO_3. The theory assumes that the thickness of this layer is at all times proportional to the square root of the concentration of SO_3 in the gas phase; in other words, that there is an adsorption equilibrium. The reaction is assumed to take place only at the boundary between the adsorption film and the platinum. The oxygen and sulfur dioxide must therefore diffuse through the film before being able to react.

This theory seems to have met with general favor and has been applied to the kinetics of many heterogeneous reactions. Dr. Langmuir proposes to modify Fink's theory slightly in that he assumes the reaction velocity to be limited not by the rate of diffusion through the adsorbed film, but rather by the rate at which the surface of the metal becomes exposed by the evaporation of single molecules from an adsorbed layer one molecule deep.

Dr. Langmuir gave in his paper a concise review of some of the fundamental principles of the kinetic theory of gases and followed this by pointing out the essential differences in his low-pressure experiments with filaments, and the conditions that would prevail if higher pressures were used.

At pressures as high as atmospheric pressure, convection currents set up by the filament produce very serious complications. At pressures of a tenth of a megabar* or less, convection currents become negligible for most purposes, but the problem is still complicated by the sharp temperature gradients that occur in the gas around the wire. At ordinary pressures, unless the velocity of the reaction is extremely small, the rate of reaction is determined largely, if not wholly, by the rate at which the reacting substances can diffuse to the surface and the products diffuse out. Under these circumstances, we should expect Nernst's theory to apply in general, but in this case we are really not measuring the velocity of a chemical reaction at all; we are merely measuring a diffusion coefficient in a gas.

On the other hand, at pressure as low as 10 bars diffusion may be considered as practically infinitely rapid. At this pressure the free path of the molecules of most gases is very close to 1 cm. This is so large, compared to the diameter of the wire, that it is evident that the molecules leaving the wire can in no way interfere with those approaching it. Under these conditions the gases don't need to diffuse through each other in the ordinary way. At such low pressures as those we may, in fact, look upon the gas as consisting of a swarm of molecules entirely independent of one another.

The velocity of the molecules around the filament is then determined by the temperature of the bulb and is entirely independent of that of the filament. There is thus no temperature gradient in the gas around the filament. The average velocity of the molecules striking the filament is definitely known, and in case two or more gases are present, the relative number of each kind of molecules striking the filament is also known, no matter how rapid the reaction may be.

An interesting feature, possible only with reactions at very low pressures, is the fact that the temperature of the molecules striking the filament is different from that of the filament itself. At ordinary pressures, because of the heat conductivity of the gas, the molecules striking a solid body are, of course, always at the same temperature as the body itself. This opens up new possibilities in studying the kinetics of reactions. The effect of separate variation in the temperature of two reacting substances can thus be studied. If it is the impact of the gas molecules against the surface of the filament which determines the velocity of the reaction, then this velocity should depend much more on the temperature of the bulb than on that of the filament, since the impact depends on relative velocity, and the velocity of the heavy tungsten atoms, even at high temperatures, is much less than that of ordinary gas molecules at room temperature. On the other hand, if the reaction velocity is determined rather by some condition of the surface of the filament, then the effect of bulb temperature will usually be negligible.

Another result of the use of low pressures is that the molecules of the products of a reaction, when they leave the filament, do not return again until after having made many collisions with the bulb. If the substance formed is a non-volatile solid, or can be condensed by cooling the bulb in liquid air, it is thus possible to make certain that the reaction does not take place as the result of two collisions, but necessarily occurs in one. In this way also it should be possible to produce many compounds which are very unstable at the temperature of the filament.

At sufficiently low pressure (about 1 or 2 bars) the molecules leaving the filament travel directly to the bulb without striking any other molecules on the way. Naturally, they have no chance of giving up any energy on the way to the bulb, and therefore (if we can speak of the temperature of a single molecule) reach the bulb with the same temperature as that with which they left the filament. This must give the most sudden cooling which it is possible to give, and there is then the minimum chance for the decomposition of the product formed if it happens to be unstable at some temperature between that filament and bulb.

Another important advantage in working at low pressures is that the velocity of even the most rapid reactions in this way can be slowed down sufficiently so that they can be studied quantitatively. The heat liberated by the reaction on the filament is usually so small as to be noticeable, or at any rate is not so large but the isothermal conditions may be maintained.

After his exceedingly interesting general exposition of what may be learned from the study of gas reactions at extremely low pressures, Dr. Langmuir discussed in detail the reactions which occur when a gas is "cleaned-up" by a heated filament. We can give here only a very brief summary of these parts of Dr. Langmuir's paper.

*1 bar = 1 dyne per sq. cm. 1 megabar = 1,000,000 bars and almost exactly = 750 mm. of mercury.

There are four classes of cleaning-up reactions.

(1) *The filament is directly attacked by the gas.*—A typical example is the clean-up of oxygen by a tungsten filament (*Journal* Am. Chem. Soc., vol. 35, p. 105, 1913). This reaction is interesting in its bearing on the theory of molecular films. Reactions between chlorine and tungsten and between carbon and oxygen were also discussed, but more briefly, under this heading.

(2) *The gas reacts with the vapor given off by the filament.*—The reactions discussed by Dr. Langmuir under this heading were the clean-up of nitrogen by a tungsten filament (*Journal* Am. Chem. Soc., vol. 35, p. 931, 1913) and by a molybdenum filament, the clean-up of carbon monoxide by tungsten, and the clean-up of oxygen by platinum.

(3) *The filament acts catalytically on the gas, producing a chemical change in the gas without any permanent change in the filament.*—A typical example is the dissociation of hydrogen into atoms in contact with a tungsten wire at low pressure (*Transactions* Am. Electrochem. Soc., vol. 20, p. 225, 1911; *Journal* Am. Chem. Soc., vol. 34, pp. 860 and 1310, 1912; vol. 35, p. 927, 1913; vol. 36, p. 1708, 1914, and vol. 37, 1915). The dissociation of the hydrogen does not occur in the space around the wire, but takes place only among the hydrogen molecules which have been absorbed or dissolved by the metal. Other examples of catalytic reactions discussed by Dr. Langmuir are the dissociation of chlorine into atoms, the dissociation of oxygen into atoms, and the reaction between carbon monoxide and oxygen in contact with platinum.

(4) *The gas is chemically changed, or is made to react with the filament by means of electric discharges through the gas.*—If a positive potential of 100 volts or so is applied to an auxiliary electrode in a bulb containing a heated filament, electrons are given off from the heated filament and these, in passing through the gas, may produce ionization. The positive ions then are attracted to the hot filament and strike it with high velocity. Under these conditions reactions often occur which otherwise would not take place. For example, if the gas is nitrogen, these positive ions will combine with the tungsten filament to form the nitride WN_2 even at temperatures where there is normally no appreciable volatilization of the tungsten.

In the reactions considered by Dr. Langmuir the velocity of the reaction is limited by the rate at which the reacting molecules come into contact with each other.

With reactions occurring on the surface of the wire, only a small fraction of the surface was in condition suitable for the reaction. The rate of reaction in these cases was limited by the rate at which the gas molecules could strike that part of the surface where the reaction could occur. In no case was there any evidence that the reaction was limited by any diffusion process in the ordinary sense.

In the case of reactions where the gas combined with vapor from the filament, the rate was again limited by the rate at which the molecules came in cantact. All those that made contact reacted.

Only in two cases was it possible to measure a velocity which was not limited by such purely physical factors. These cases were the combination of nitrogen with molybdenum vapor and the attack of tungsten filament by carbon monoxide with low bulb temperatures. It is remarkable that in both these cases the temperature coefficient of the reaction velocity was strongly negative. In all the other reactions the large positive temperature coefficient was due to the fact that the rate of evaporation of the filaments or of absorbed materials on them increases so rapidly with temperature.

Dr. Langmuir did not mean to imply that all truly chemical reactions must have negative temperature coefficients, but the results strongly suggest that such chemical reactions are very common, but that their effects are masked by other physical factors having large positive temperature coefficients.

The number of chemical reactions previously known which have negative temperature coefficients is extremely small. Bodenstein cites one case, while Strutt found that atomic nitrogen recombines to form molecules much more rapidly at low temperatures than at high, and reasoned that a high translational velocity of the molecule should in general hinder rather than hasten the reaction. Strutt considered that rotational velocity of the molecules, on the other hand, favors the reaction and that this factor in the majority of reactions greatly outweighs that of the translational velocity. Thus reactions between atoms should always have negative temperature coefficients, since atoms cannot have rotational energy. Dr. Langmuir's work lends further support to Strutt's views.

The viewpoint developed as a result of this work with low pressure reactions is undoubtedly applicable to reactions at high pressures and also to reactions between solids and liquids. Dr. Langmuir expressed the hope that further work will lead in a similar way to a better understanding of the mechanism of homogeneous reactions.

The Proposed British Dyestuff Industry

A German Opinion on Great Britain's Prospects

In view of the serious attempts which are being made at present in Great Britain to create a British dyestuff industry, it is of particular interest to read what a prominent representative of the German chemical industries has to say about these endeavors.

In the *Chemiker Zeitung* of Feb. 13, 1915, Dr. Otto N. Witt, who is professor of applied chemistry at the Charlottenburg Institute of Technology and who was employed in former years as a chemist of some British aniline-dye works, publishes an article on "The New English Dyestuff Industry," which we reproduce slightly abstracted in translation:

"The desire to develop a strong and complete coal-tar industry, the most important branch of which must be the manufacture of dyestuffs, is not only comprehensible but logical and natural in every country which owns large coal fields and has an extensive iron industry. Such a country is bound to install by-product coke ovens and will, therefore, find it necessary to make profitable use of the abundant quantities of the tar.

"It is also easy to understand that during the present war, when the interchange of products between nations becomes difficult and frequently impossible, the lack of a coal-tar industry makes itself more felt than in days of peace, when a highly organized shipping trade meets every demand. Thus it has happened that not only Great Britain, but also the United States of America, have been thinking of the establishment of a coal-tar industry.

"In both countries these efforts would have been made at an earlier date were it not for the fact that for many years an entirely unjustified prejudice against cooking in by-product ovens had existed, which only recently has been overcome.

"If, therefore, the desire for a coal-tar industry in England and in the United States is something that was to be expected in the course of natural development, neverthless, it is grotesque that in the case of England this development is an outgrowth of the national idea that Great Britain has been harmed by Germany's technical development, although the latter was but a natural

development of a healthy, well-governed people with the will to live. . . .

"In many publications I have pointed out that no country is able to transplant the technical creations of another country as a whole. Therefore I hardly think that England's present efforts to establish a dyestuff industry after the German model will be a success. I will try to give the reasons for this opinion.

"I have formerly shown that the color industry has never been developed in England to any great importance, although it was started there under the most favorable conditions. For many years England had a monopoly on all coal-tar products; besides, by the war of 1870-71, she had become free from all competition in the dyestuff industry, so that she had the best opportunity for getting such a strong foothold among the consumers in the whole world that it would have been difficult to compete against her. From the chemical point of view the dyestuffs, although not numerous, which at that time were made in English works were absolutely equal to the products of continental Europe, as I know from my own experience.

"If some of the processes of manufacture were somewhat cumbersome, according to our present views, this was also true in many instances on the Continent, while at the same time the prices, even with expensive processes of manufacture, left a sufficient profit. The nature of these processes frequently depended on local conditions. As an instance I mention the manufacture of the fine alcohol blues. In the Swiss works they were made by repeated extraction of the crude blue by alcohol which at that time was exempt from taxes in Switzerland. In England, where always a high tax was levied on alcohol, an ingenious process was used, by which the blue base was dissolved in aniline oil; an equivalent quantity of aniline salt was then added, whereby the chlorhydrates of the triphenylrosanilines were formed. Of these that of the fine blue is quite insoluble in aniline; it therefore crystallizes out of the solution in magnificent leaves, glittering like gold, while the ordinary blue was recovered from the motherlye by driving the aniline over with steam. In this manner and without the use of alcohol, although with the use of a solvent expensive at that time, such a complete separation of the two blues was accomplished in one operation that even to-day I would prefer this process above any other, if, perhaps for scientific purposes, it was necessary to completely separate the mixture of dyes resulting from introducing the phenyl group into ordinary rosaniline. In the industry, to be sure, the demand for a good light blue has been filled in a simpler manner by the use of pararosaniline, but this was accomplished only several years later.

"If, therefore, ability can not be denied to the older English color industry why has it accomplished so little? To this the English of to-day have the easy answer that the German competition has been the cause. But the unbiased observer will contend that of two competitors the one who was first on the spot and worked under more favorable conditions has the advantage. This was undoubtedly England. What was her shortcoming?

"Not one but several causes have acted together to bring about the result. One of them has been discussed to distraction on both sides of the Channel. It is the co-operation of scientific research with the industry. The English chemists, who are not numerous, but some of whom are very prominent, have emphasized this point in order to advocate an increase of their scientific and research laboratories. They conclude by way of inference that England, if provided with as many scientific laboratories as Germany would produce as large a number of well-trained chemists for her industry as Germany does. They overlook, however, that it does not suit the character of the young Englishman to be trained to be a scientific assistant in the same manner as the German student who, owing to the system of examinations and promotions, is obliged for a time to do independent research work before he can think of earning his daily bread. Many a student would perhaps not do the former if he were not compelled to. After, however, he has gone through this wholesome training the acquired scientific habit will mostly stay with him during his later professional life. That is, if we want to be quite frank, the true reason for interrelation between science and industry in Germany. If we had to rely only on those who have been born with a desire for research work, the number of scientific assistants in the German industry would not be as large as it actually is.

"It might be said that Germany has established also in her industry a general compulsory service (the English call it "militarism") which bears such brilliant results in her army. Not every soldier can be a strategical genius. In the same way the great majority of the thousands of capable and reliable chemical engineers, whom Germany has at her disposition, do not claim to perform original and inventive work. They are quite content with the rôle of intelligent and reliable factors in a great system created and more and more developed in the course of time by the genius of a few organizers, which, once created, is self-maintaining and produces its own leaders as in a well-organized military power. It would be a pity if in our educational courses and in our professional work we were lacking this strict organization. The situation would then be as it is in England, where every young man from his sixteenth or seventeenth year thinks of earning a living and if he does not his parents or relatives will make him understand that that is the proper thing for him to do. In Germany there are thousands of fathers who starve so that their sons might have a college education; these are unknown in England. There it is the privilege of the well-to-do "upper ten thousands" to send their sons to the universities, at the same time giving them such large allowances that the young men are in a position to spend more of their time on expensive sport than on scientific work. As a consequence, the scientific institutes of the universities and especially their chemical laboratories must be called poorly equipped from our point of view. What they have is all that is necessary to keep up the style of the English universities as it is fixed by traditions of centuries.

"Those laboratories in England which are not quite as narrowly framed as the national universities proper and which enjoy more freedom are few in number, but they are the real cultivating grounds of chemical science in England. They serve the requirements of those who have an inborn desire to devote themselves to research work and who have the means to do so. But as the means are often lacking, nearly all of these institutions have so-called "evening classes," in which for a modest remuneration such people can partake whose day-time is taken up by their trade, but who have nevertheless a desire for scientific studies. That these courses are in many instances very thorough must be mentioned with praise, but it is evident that they cannot give advanced instructions for experimental work, not to speak of independent research work.

"These conditions are the reason that the English nation, perhaps more frequently than the German, has produced able, occasionally even ingenious, autodidacts in chemistry (I only mention Gilchrist Thomas), but they are also responsible for the fact that the great army of all-around useful, scientifically well-trained as-

sistants, as Germany has, to the good fortune of her industry, is entirely missing in England.

"It is not impossible that in England these conditions may change as completely as has been the case with some other things. Such a change is, however, as little probable as is the overcoming of two other evils in the color industry.

"From a technical point of view, the English industry has suffered from a lack of organization and of working records. This evil is connected more closely than may appear at the first glance with the lack of scientifically trained assistants. The English factories must, in many cases, entrust with the management of their works people who belong not even to the "semi-educated class," although they are frequently very handy and intelligent. As a natural consequence the working records in some instances are limited to chalkmarks. The more manifold a manufacturing process, the more dangerous is the lack of control.

This may perhaps have been remedied in some works, since the Americans have raised the control system to a kind of science, mainly in machine shops, and have thereby directed the attention of larger classes to the importance of scientific management. Nevertheless I doubt whether the greater number of the works of the English chemical industry have an organization which can be compared to that in most German plants. For the German works organization has been created chiefly by the talent of a few scientifically trained chemists who managed to permeate even the dry array of figures with the live spirit of investigation.

"Finally it was the insufficient commercial organization that was the greatest detriment to the older English color industry. This shortcoming has been openly and frequently admitted by the English themselves for other branches of industry, and there have always been people in England who have recommended to their countrymen to take as a model the activity and circumspection of the German businessman. But they evidently have often preached to deaf ears.

"We [the Germans] are accustomed to look upon the English as very able businessmen. They certainly are as far as the spirit of enterprise, far-sightedness and large commercial speculations are concerned. But the English are less fit for the organization of a trade which, like the sale of dyestuffs and of fine chemical products generally, requires that continuously all small details are observed without losing sight of the great viewpoints. For this purpose the many Germans who heretofore used to earn their bread in England have been useful members of the English commercial world and their absence will be seriously felt when, after the war, they are released from the detention camps and leave England.

"In the foregoing I think I have enumerated the most important reasons why the older English color industry, though started under the most favorable auspices, failed to keep step with the younger Germany industry and, in spite of all the beautiful speeches, has been forced more and more to the background. According to the English view, these are mere details. The new industry is to be started with the aid of the Government which is to advance some millions, for the larger part of which, however, the consumers of the new dyestuffs are to be held responsible.

"How about these dyestuffs? That they will leave nothing to be desired is, according to the English view, warranted by the names of the members of various committees which have been formed for the organization of this affair. Very many of these members I know personally well. These gentlemen, mostly well advanced in years, none of whom has so far been prominently active in the color industry, will hardly be able to build a large factory and to manage it. In addition there are in the committee several, probably younger men, whom I do not know and among whom there are probably those organizing talents who now, all at once, shall stamp out of the ground what England for more than fifty years has in vain cried for and aimed at—a great organic chemical industry, strong enough to compete against the German industry in England and in the world's markets, and at the same time able to pay interest on the capital advanced for its foundation.

"In the latter point, which must not be forgotten, there lies the greatest difficulty of the whole enterprise. All the others may be overcome with the aid of an exceptionally favorable chain of circumstances. Whether the government or the textile industry of England advances the required large capital neither one nor the other can waive an adequate interest and amortization. This means that 12 to 15 per cent of the capital invested must be earned before any profit can be made. If we consider that every new enterprise has its infancy losses, that not only the new factories but in many instances also the conditions for their existence have to be created, no favorable prognosis can be made for a profitable development.

"The German and Swiss color works have accumulated in the course of many decades not only large reserves by most cautious and rational financing, but they have also written off the book value of their plants to a minimum. This ensures a continuous source of profit which is lacking for every new enterprise of the same kind. For this reason the founding of new color works, formerly so popular, has been discontinued in continental Europe entirely. Every financier to whom such a scheme would be proposed would immediately realize that the new enterprise would not be able to compete against the old large works. But England wants to make the experiment, after having heretofore always complained that her existing color works cannot exist against the German competition. If these factories had been managed chemically, technically and commercially in the right manner and if they had accumulated reasonable reserves they would have worked under nearly the same conditions as the German ones. Like these, they could have expanded long ago to very large enterprises which could have met the German competition under equal conditions. As they have not accomplished this, a new large enterprise is now to be founded, which under worse conditions is expected to achieve the success that was denied to the old works.

"Success of this undertaking could leave Germany, of course, entirely disinterested if it would not bring about certain very remarkable consequences. Not so much for the German color industry, which may be confidently relied upon to meet the new competition, but in the first place for the German textile industry. It cannot be denied that in a large number of products, and especially in those which by their higher value left a greater margin for clear profit to be realized, as fine worsteds and other woolen cloths, fine-filed cottons and linens, the German industry has not been equal to the English, as is evident from the import statistics. Just this English industry has heretofore largely used German dyestuffs, and just this industry is supposed to finance the new English color industry, or, in other words, to bear the unavoidable damage which it is bound to do. That means, of course, a weakening of this heretofore strongly founded English textile industry and consequently a strengthening of the German one. The latter must and will under all circumstances, after the war, strive to produce for the home market many articles which heretofore were bought from England, and the

total value of which probably balances the value of the chemicals exported from Germany to England. It can do so the more readily as long as England harms and cripples the exporting part of her own industry by new enterprises which are not created in a rational, commercial spirit, but which are the offspring of the passions of envy and of jealousy. For the German color industry the result will be that it will be able to dispose of a large part of what it has heretofore exported to England in the home market due to the expansion of the German textile industry.

"The whole affair reminds one very vividly of the famous 'Made in Germany.' The demand for this inscription on all German goods was a measure dictated by jealousy and based upon the supposed inferiority of the German products, which inferiority was so long talked of in England that it finally was believed. To-day it is generally known that the strict observation of this measure has furnished uncounted millions to the German trade. I can see no reason for any apprehensions on the part of Germany about the creation of the new English color industry."

Recent Chemical and Metallurgical Patents

IRON AND STEEL

Interlocking Brick for Hot-Blast Stoves.—In Fig. 1 is shown a form of interlocking brick for hot-blast stoves, patented by EDWIN E. SLICK, of Westmont Borough, Pa. The idea is to provide a brick which cannot become broken, shifted or thrown out of alignment due to the extreme changes of temperature which occur in such stoves, and the sudden blasts or explosions which sometimes occur. The drawing at the left of Fig. 1 shows a top plan view of a portion of brick work as constructed of the interlocking bricks, which are shown in plan and elevation at the upper and lower right respectively. (1,130,031, March 2, 1915.)

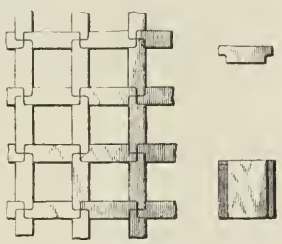

FIG. 1 — INTERLOCKING BRICK FOR HOT-BLAST STOVES

Alloy for Dynamo-Electric Purposes.—A patent of WALTER RÜPEL, of Westend, near Berlin, Germany relates to a process of manufacturing an alloy of iron technically free from silicon, phosphorus and manganese, and of a corresponding admixture of copper. The process consists in deoxidizing purified and superoxidized iron by means of a small quantity of alkali-earth metal added in the form of an alloy with copper. For example, calcium, equal to 4 per cent of the copper to be used, may be added in the form of an alloy with copper. The result will be an iron almost free from Si, Mn, P and C. (1,130,678, March 2, 1915.)

Plating or Galvanizing Machine.—Apparatus for plating or galvanizing structural bars, pipe and other objects of considerable length, is patented by CONSTANTINE G. MILLER, of Chicago, Ill., the patent being assigned to the Meaker Company. Previous attempts to galvanize angles and channels have been unsatisfactory for the reason that the gasing of the electrolyte permits an accumulation of hydrogen bubbles beneath the cavities of the bar, and thus prevent uniform plating. The present apparatus consists of a tank or trough through which the pieces to be galvanized are passed. The treatment is designed to be continuous and to yield uniform plating. The pieces to be treated are delivered into the machine on cathode bars, above and below which are supported suitable anodes. Mechanical means are provided for transporting the pieces through the trough, and also for periodically turning them over so that accumulations of hydrogen are prevented. The agitation of the electrolyte, as well as the shock of the blow in turning the piece, serves to displace gaseous bubbles, keeping the plating surface clean. (1,128,481, Feb. 16, 1915.)

Gold and Silver

Vacuum Slime-Filter.—Apparatus adapted to filter ore-slime in the cyanide process, shown in plan and sectional elevation in Figs. 2 and 3, respectively, is patented by CHARLES G. OSGOOD, of Tonopah, Nevada. The patent is assigned to the Montana-Tonopah Mines Co. In general plan and method of operation the apparatus

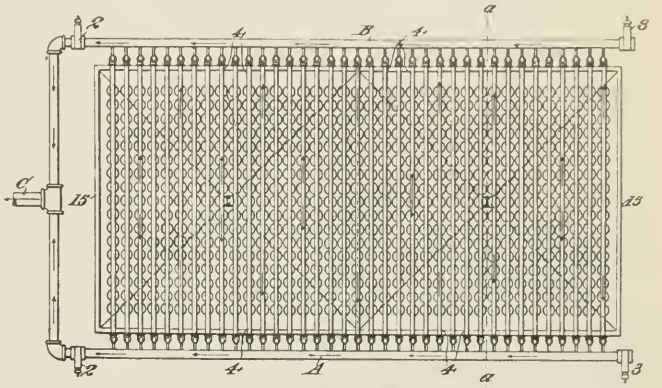

FIG. 2—VACUUM SLIME FILTER

resembles the stationary-leaf type of filter, with a large number of filter spikes substituted for leaves. Referring to the figures, the spikes 5 are supported from cross headers 4, which are all connected with manifold pipes A and B. The manifold pipes join at C and are in connection with a suitable pump, not shown. The entire filtering apparatus is contained in a tank 15. The spikes are formed with a tapered core of rectangular cross-section and having longitudinal corrugations on the sides, and a filter fabric enclosing the core. The inventor claims superiority over the leaf-type of filter in capacity per unit of space, economy and convenience of operation, and adaptability to various applications.

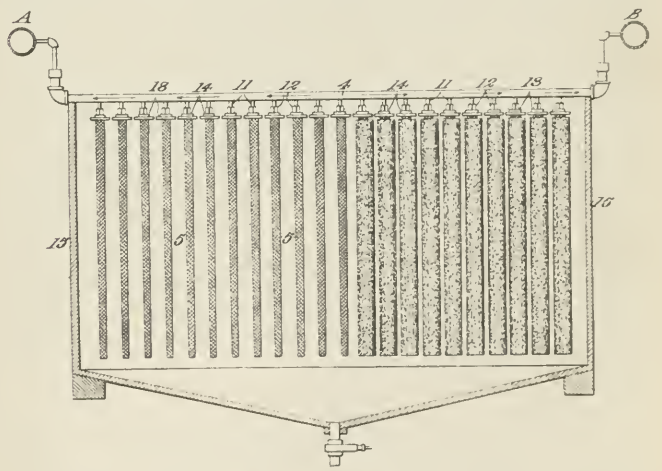

FIG. 3—VACUUM SLIME FILTER

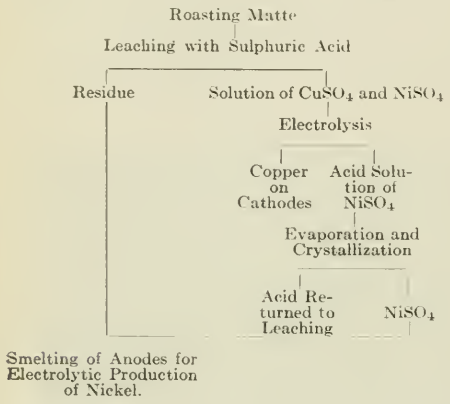
It is further claimed the invention obviates certain difficulties encountered in leaf filters, such as unequal building of the cake, breaking and fracturing of the same, and cleaning of the filter leaf. (1,128,495, Feb. 16, 1915.)

Copper, Nickel and Zinc

Refining Copper-Nickel Matte.—In several patents recently granted to N. V. HYBINETTE, of Christiania,

Norway, the inventor discloses improvements on his method of refining copper-nickel matte which was noted in this journal, January, 1906. According to that process the matte was roasted, leached to remove excess of copper, smelted and cast into anodes and also into slabs for cementation of copper from the electrolyte containing copper and nickel in the form of sulphates, thereby regenerating the electrolyte in nickel, the copper replacing the nickel in the slabs. The process of producing the copper-nickel anodes is shown below.



The anodes thus produced are electrolyzed in an acid nickel sulphate solution, whereupon copper is cemented out from the solution on metallic slabs. A special form of cell is provided for this part of the operation. The inventor previously prescribed copper-nickel free from sulphur, carbon and silicon as the material for the metal slabs on which to cement the copper. He has now discovered that cementation is possible on slabs of copper-nickel containing 4 to 8 per cent sulphur, cast from a blast furnace, provided that the slabs have been used previously as anodes in a nickel-plating tank, thereby preparing their surfaces in such a way that cementation will take place. (1,128,313-4-5-6, Feb. 16, 1915.)

Removal of Cadmium from Zinc Ores.—According to a patent granted to Gilbert Rigg, of Palmerton, N. J., and assigned by him to the New Jersey Zinc Co., cadmium can be removed from zinc ores by leaching the ore with water containing sulphuric acid in sufficient amount to convert the cadmium oxide to sulphate. Even when the sulphuric acid radical is already combined with zinc as zinc sulphate, as in roasted ore, the leaching of such ore with water will result in the conversion of cadmium to the sulphate and its dissolution in water. In practice, zinc sulphide ore would be roasted and leached with water at or near the boiling point. The small amount of zinc sulphate left in the roasted ore would suffice to convert the cadmium into sulphate which would then be dissolved in the leaching water. Preferably the roasted ore would be introduced into the leaching solution rather than the reverse. (1,129,904, March 2, 1915.)

Tungsten

A process for producing tungsten powder is patented by Robert Rafn, of Porsgrund, Norway, and assigned to the General Electric Co. The production of amorphous tungsten powder by reduction of tungsten trioxide is usually difficult of accomplishment, as a crystalline product most often results. The inventor has shown, however, that by making the reduction in two stages, first with ammonia gas at red heat, producing the so-called blue tungsten oxide, and then with hydrogen at cherry-red heat, the resulting product is a tungsten powder of remarkable fineness. (1,130,197, March 2, 1915.)

Metallurgical Apparatus

Mixing-Drum for Ore-Flotation.—In Fig. 4 is shown a cross-sectional view of a drum patented by J. M. Callow, of Salt Lake City, Utah, for mixing and aerating ore pulps for treatment by the flotation process. The apparatus is designed to accomplish its purpose by less violent means than is usually used in the propeller type of mixer. Hitherto it has been customary to agitate and aerate the mixture and form the frothy float in one vessel; but in the present invention it is designed to mix and aerate the pulp in one vessel, namely, the drum under consideration, without forming a froth, and then deliver the mixture to another vessel or cell in which the froth is formed and recovered with the accompanying mineral.

The mixing-drum consists of a shell A, within which is a lining 16 of porous material adapted to permit the passage of air but not pulp and water. This lining is

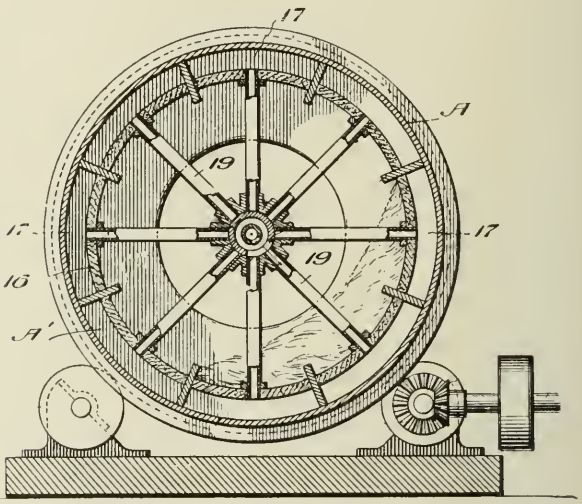


FIG. 4—MIXING-DRUM FOR ORE FLOTATION

spaced apart from the outer casing, forming chambers 17 between the two. The chambers are supplied with a series of pipes 19, for admitting air under pressure; and by means of a suitable valve the air is admitted into successive chambers during the rotation of the drum. Agitation and aeration are thus accomplished as the pulp flows through the drum from feed to discharge end. (1,124,854, Jan. 12, 1915.)

Metallurgical Furnaces

Electric Casting Furnace.—An electric furnace specially adapted to the cast of metals or alloys of high melting point is patented by A. L. J. Queneau, of Philadelphia, Pa. (now in the war with the French army). The furnace consists of a shell of suitable form, containing a crucible in which the melting is done. A combined casting nozzle and electrode extends into the crucible. Both the crucible and nozzle are kept at a high temperature to maintain the metal in a fluid condition and to prevent it from chilling in the nozzle. Means are provided for producing within the crucible a pressure of about 100 lb. per square inch to force the molten metal out through the casting nozzle and into the mold. (1,126,079, Jan. 26, 1915.)

Lining Furnaces by Cement Gun and Torch.—The necessity of keeping furnace walls in good repair, and the obvious difficulty and expense which attend the ordinary methods of doing this work, has led Alfred Schwarz, of New York City, to devise a means of forming and repairing furnace walls in an improved manner. The apparatus required is similar to that used in cement work, the so-called cement gun, in combina-

tion with a high-temperature flame. In operation the ground refractory material to be used for the lining is projected through the gun at velocities ranging from 3000 to 15,000 ft. per minute. As the particles leave the gun they are forced onto the wall and embedded therein in a fused condition, due to the softening effect of the flame. The process may be used while the furnace is hot or cold. As the cement gun and torch are well-known machines, the invention lies in the process of forming or repairing walls of furnaces by projecting comminuted refractory material at a high velocity against the wall and subjecting the wall to a fusing temperature at the time and point of application. (1,125,741, Jan. 19, 1915.)

Another process of forming furnace walls and preventing their disintegration due to heat is patented by JOSEF HEMMER, of Veitsch, Austria-Hungary. Pieces of iron are mixed in the mortar, in which the bricks are laid. (1,123,874, Jan. 5, 1915.)

Chemical Engineering

Fixation of Atmospheric Nitrogen.—A patent by SAMUEL PEACOCK (assigned to the International Agricultural Corporation) relates to a new nitride process of the same general type as the Serpek process. The inventor starts with feldspar which is finely ground and mixed with carbon. He uses for every pound of alumina 0.75 lb. of carbon, for each pound of potash (K_2O) 0.3 lb. of carbon; and for each pound of silica 0.8 lb. of carbon. This mixture is heated in an electric furnace, and as the temperature rises to say 2500 deg. C., a flow of nitrogen gas is maintained through or over the mixture. There is stated to result the formation of a higher carbide of aluminium Al_2C_3 and of potassium carbide K_2C, and this is said to be followed by the formation of carbonitrides of aluminium and potassium, respectively; the following equations being given $Al_2C_3 + 3N_2 = Al_2N_2C_3N_4$ and $3K_2C + 3N_2 = K_6N_2C_3N_4$. Both of these carbo-nitrides are volatile at high temperatures employed, and may be conveniently sucked out of the furnace and collected in bag separators or forced into a digestor. In the digestor the carbo-nitrides are subjected "to the action of superheated steam at a pressure of say 5 to 7 atmospheres, whereupon the following reactions take place, producing alumina, potassium carbonate and ammonia: $Al_2N_2.C_3N_4 + 9H_2O = Al_2O_3 + 3CO_2 + 6NH_3$ $K_6N_2.C_3N_4 + 9H_2O = 3K_2CO_3 + 6NH_3$. Of course, more or less silicon carbo-nitride $SiN_4.C_6N_4$ will also form, but at the high temperature of the furnace charge, it will practically all dissociate and remain in the form of a carbide. By now cutting off the nitrogen and raising the temperature of the furnace to say 2800 deg. C., the well-known product siloxicon, Si_2C_2O, may be obtained, as well as other oxycarbides; and by still further increasing the temperature up to say 3500 deg. C., the lower silicon carbide SiC may be obtained. It will thus be seen that my invention takes advantage of the high temperature necessary to make siloxicon, or silicon carbide, to produce carbo-nitride, without an extra cost of energy, and that from these carbides alumina, potassium carbonate, and ammonia may be produced. Further, the alumina and potash are separated from the mineral and the nitrogen fixation occurs before the temperatures necessary for the formation of the silicon compounds are reached; so that when said last mentioned compounds are to be formed the proper proportions of silica are present in the charge. It therefore follows that the above by-products are obtained, without interfering with the regular process of making the said silicon compounds." (1,129,506, Feb. 23, 1915.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

The Consulting Metallurgist and Metallurgical Investigations is the title of a forceful and timely article by Mr. W. B. BLYTH, published in the *Proceedings* of the Australasian Institute of Mining Engineers, No. 16, 1914. The article relates to the work of the consulting metallurgist in the cyanidation of gold and silver ores, and gives many pertinent suggestions regarding the testing of ores, designing and operation of plants, and investigation of existing plants. In addition to technical data, the article contains much wholesome advice. A few of the important matters are here briefly reported.

The author points out the difficulty of interpreting probable commercial results from small scale tests, but adds that "common sense, resource and dependable apparatus are the most valuable assets in comparing work of this nature."

Attention is called to the necessity for co-operation between the mining, the mechanical and the metallurgical engineer, in order to get the best economic results and to safeguard the investigator in matters on which he is not expert. In order to avoid future misunderstanding with the directors of a company it is well to limit the anticipated extraction to a given tonnage, so that future overloading of the plant, with its attendant lowering of extraction, cannot be made to reflect on the investigator.

In testing for the treatment of raw sulphide ores and concentrates dry crushing will give faulty results for the following reasons:

(*a*) That dry crushing and screening is positive crushing, and the softer particles of high specific gravity are not necessarily crushed finer than the hard particles of low specific gravity. Consequently, although screen tests may show that the whole product is fine enough, yet in reality the gangue particles are probably too fine and the sulphide not nearly fine enough. The percentage of colloids in a sample crushed wet to pass a 150-mesh screen is enormously in excess of that in the same sample crushed dry.

(*b*) An excess of abraded iron is produced in dry crushing, and the heat generated expedites oxidation in sulphides that are liable to rapid oxidation—both disastrous factors, under certain conditions, to subsequent cyanide treatment.

It is pointed out that abraded iron is innocuous if the solution is kept alkaline with CaO and no heat be generated. Once oxidized, however, the iron precipitates ferrous hydroxide with lime, and ferrocyanide is formed. The resulting conditions are such that good results are impossible. Ferrocyanide in itself is harmless, but its presence suggests that poor conditions have existed or do exist. Graphite is without effect except that it acts like oil in the flotation process and surrounds mineral with a scum which prevents extraction. The effect of pyrrhotite is not clearly understood. In some cases it acts as a precipitant.

Much stress is laid on the preparation of the sample on which tests and assays are made. The metallurgical engineer is urged to know for himself the nature of underground conditions, the quality and quantity of ore, and the collection of the samples. "Expecting sharp criticism from mining engineers, perhaps few are competent to select, unaided, a representative sample from a mine for the purpose desired."

The investigation of the hardness of the ore is necessary in order to determine grinding conditions. The author's method of computing regrinding factors was outlined in this journal, August, 1914, page 537.

Discrepancies between laboratory and plant roasting are discussed at length. Time is believed by the author to be the most notable factor in these discrepancies. In a comparative test he found that whereas ore remained in a furnace for several hours, attaining its temperature gradually, a muffle roast in the laboratory is complete in

45 minutes. His apparatus and method for getting comparative results are as follows:

"A cast-iron dish 4 in. deep, divided into two compartments, is made to closely fit into an ordinary wind assay furnace fired with coke. The fire is started and the shaft filled with cold coke, well rammed. The cast-iron dish is then placed in position on top of the fire and the edges packed tight with small coke. A charge of the ore to be tested is placed in one compartment (1000 grm.), while a charge of an ore on which dry-crushing and cyaniding results are already proved is placed in the other. The draught is kept well back, and the heat gradually raised with constant rabbling. In about 30 min. sulphur should commence to come off, and this should all be off in two hours. After two hours the heat can be raised as much as possible, and finally the lid of the furnace is closed for about 10 min. Rabbling must be carried on carefully all the time, as any fritting precludes success. If subsequent cyaniding experiments on the ore (on which the process is proved) give plant results, then the results obtained on the new ore may be accepted as reliable. By this means the writer has obtained reliable results which have been borne out in the plant."

Amalgamation tests on a small scale cannot be relied upon, and inasmuch as amalgamation plays such a relatively unimportant part in cyanidation nowadays, the author prefers merely to amalgamate in a pan for the removal of coarse gold and not to indicate what saving can be made by that process.

Leaching tests usually give dependable results. They should be made in a high column, say, 6 ft., and aeration of the sand and solutions should be attempted.

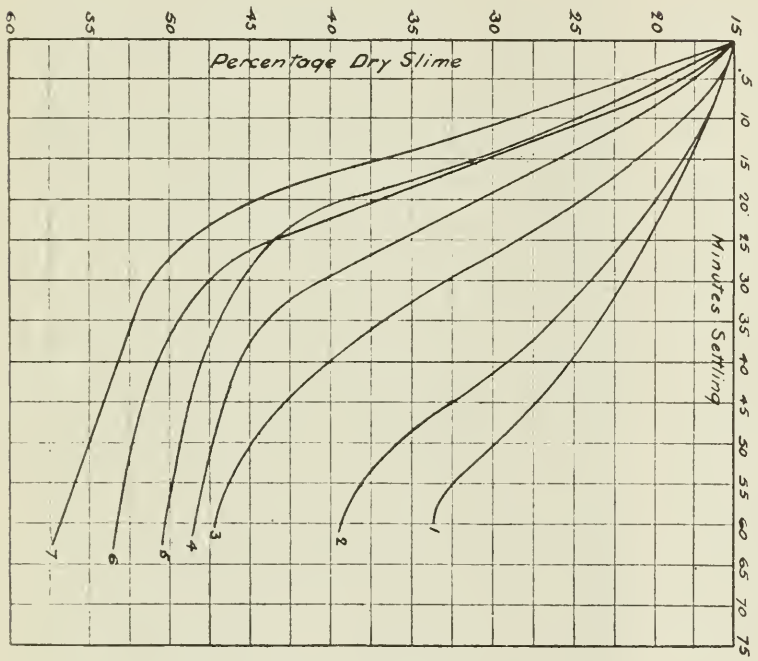

FIG. 1—SLIME SETTLEMENT CHART

The determination of the slime-settling rate is an important matter. The author has elaborated a standard slime-settlement chart, shown in Fig. 1, based on tests conducted as follows:

Two 1000 cc measuring flasks were obtained of similar height (15 in.). A 15 per cent pulp of the slime to be tested was introduced into the flask. The pulping medium tested 0.05 per cent KCy and 0.013 per cent CaO; 15 per cent was determined on as representing a fair plant thickness. The test was conducted on the sampled slime from a number of different mines which had efficient settlement plant already installed. The settlement test was conducted in each case under identical conditions with regard to the determining factors, but the particular mine water was used in each case. There are mine waters varying from 0.1 per cent to 26 per cent of solids in Western Australia, and this is a factor of great importance in making settlement tests. Settlement was allowed for one hour in each case, and two tests were conducted—one in the alkaline cyanide solution already described, and the other in the ordinary non-alkaline mine water. The diagram (Fig. 1) shows the tests conducted in the alkaline solution only. The diagram is of considerable value in designing plants, as, knowing the settlement area for a given tonnage of slime on the mines illustrated on the diagram, it is only necessary to compare a settlement test conducted under similar conditions to arrive at the settlement area required to do definite work on the ore under examination."

Referring to new processes designed to supplant proved methods, the author wisely observes: "Let the old-established producing mine do the experimental work. The new producer has too much at stake to take any chances."

In making vacuum-filter capacity tests care must be taken to filter the product in exactly the same condition experimentally as it will be obtained in the plant. The question of replacement of pregnant solution with wash solutions is a criterion of the work. A good way to conduct these tests is to take a series of solution samples from the vacuum pump discharge every five minutes during the wash. When the assays are arranged in graphic form they show the replacement of gold solution by barren wash, and when two washes are used the replacement of barren solution by water is indicated.

Special attention is directed to the assay of slime residue and the probability that such assays will be faulty unless the greatest care is exercised. The losses which may occur in drying the sample, especially the losses of dissolved gold in the residue, are remarkable. This point was touched on at some length in this journal, February, 1915, page 119. The use of precipitants is advisable before drying and assaying. Cuprous chloride or Whitby's mixture (copper sulphate, sodium sulphite and sulphuric acid) are suitable precipitants.

In estimating working costs after having determined the economic solution of the extraction problem, the metallurgist should lay out the flow sheet in detail and estimate treatment costs. The type of plant required must be determined by sketching out in detail all the possible economic alterations. Then detailed treatment costs should be prepared, and a balance sheet made showing the net result of each alternative scheme. "Cost estimates can only be safely entrusted to experienced and conservative operators." Fixed and variable costs must be considered, especially the latter, as they vary with each individual ore.

Determination of Gold and Silver in Cyanide Solutions.—In the *Bulletin* of the American Institute of Mining Engineers for February, 1914, Mr. L. W. Bahney, of New Haven, Conn., presents a method for determining gold and silver in cyanide solutions, of which we present an abstract. Five assay tons of solution (146 cc.) is placed in a 250-cc. beaker. Add successively 20 cc. of a 20 per cent solution of lead acetate and 15 cc. concentrated hydrochloric acid. Then place a ¼-in. rod of zinc in the beaker and boil the solution for five minutes. Fill with cold water; then decant about half, and again fill with cold water. Withdraw the zinc rod, freeing it from particles of lead sponge. Wash the sponge several times with water, press sponge together to remove water, decant and wash again. Place the sponge in a piece of sheet lead 2 in. square, fold and cupel. In case the sponge does not cohere in a single piece it may be filtered on a piece of lead foil formed into a cone and containing some test lead.

Copper

Oil-Fired Reverberatory Smelting at Nevada Consolidated Copper Co.—In a paper presented at the February meeting of the American Institute of Mining Engineers Mr. R. E. H. Pomeroy gave some data on reverberatory copper smelting at McGill, Nevada. The furnace is 132 ft. long with an average width of 18 ft. 10 in. at the skim-line level. It is equipped with two 400-B.hp Stirling waste-heat boilers. The fuel is California crude petroleum of 16.5 deg. B. sp. gr., and with a flash point of 199 deg. Fahr. It is heated to 200

Average..	59.9	7.6	12.4	4.9	12.7	2.5

Factors affecting efficient combustion of the fuel:
1. The use of a burner to give a proper atomization of the oil so as to obtain a long uniform flame without overheating any portion of the furnace.
2. Regulation of the draft so as to furnish the proper mixture of gases for complete combustion in the furnace.
Factors affecting the operation of the furnace proper:
1. Careful preparation of the charge by adequate mixing of all ingredients before charging.
2. Addition of enough lime rock, preferably coarse, to produce an active boiling in the furnace.
3. Maintaining a deep bath of molten matte to equalize and distribute the heat over the whole of the hearth.
4. Frequent skimming so as to carry only a thin layer of slag over the matte bath.
5. Operating the furnace for the best smelting conditions, ignoring the waste-heat boilers as factors in the power supply.
Factors affecting the life of the furnace:
1. The furnace roof set high over the hottest portion of the hearth.
2. Frequent fettling to protect the side walls.
3. Frequent charging and active charge mixtures to avoid floater and blanket formation requiring excessive firing.

Metallurgical and Chemical Engineering in Great Britain

(By our London correspondent)

Birmingham Section, Institute of Metals

Mr. T. J. Baker, Sr.'s paper on "Bronzing Processes Suitable for Brass and Copper" was read on Jan. 26, and dealt with steel-bronzing, with possibilities of variation in coloring on the same object, by stopping out, or employing an intermediate coppering bath for the brass: also the production of black, deep blue and antique effects. The variety of colors which can be obtained on brass-work, such as gold, crimson, purple, blue and lavender, though not employed commercially, suggest a field worthy of investigation by the producers of jewelery.

Refractory Materials and the War

In a contribution to the *Journal* of the Royal Society of Arts, Mr. Alfred B. Searle points out that the importation of bricks for building coke ovens and other furnaces from Belgium has ceased, and that consequently efforts are being made in this country to bring firebricks up to the specification required by the continental builders.

Similarly retorts for the manufacture of coal gas are not now obtained from Germany. The relative values here appear to be more indeterminate, as some German engineers imported British retorts, and vice versa.

Iron and Steel Institute Dinner

The annual meeting of the Iron and Steel Institute will be held by kind permission at the Institution of Civil Engineers on Thursday and Friday, May 13 and 14, 1915. The date for the annual dinner has been provisionally given as May 13 but this will be the subject of a future announcement.

Scottish Oil Trade

A Scotch company have erected a plant at Addrewell for operation of a German patent process, the rights of which were acquired last spring for the conversion of oil products into commercial materials.

Institute of Industry and Commerce

The interests of chemical manufacturers in this country are receiving the attention of a central committee which meets early in February at the offices of the Institute of Industry and Commerce, Strand. A preliminary meeting has already been held.

Platinum in Russia

The British vice-consul at Ekatermburg gives some interesting notes on the platinum position. The present situation has, apparently, resulted in an interruption to the regular export trade, due to continental buyers not taking up contracts, and there should therefore be temporarily more platinum on the market than usual.

Heating of Mines

The heat in deep mines was treated of by Professor Cadinaw, D.Sc., in his lecture at Ashby-de-la-Zouch on Jan. 23. He took the sources of heat under three heads: (1) Heat due to rock temperature; (2) heat due to compression of the air, and (3) heat due to oxidation. Heat could not be modified by the introduction of moisture in deep mines, as this was detrimental to workmen, and it was also imperative in deep work to keep the air dry. For the prevention of oxidation the following means appeared the most effective: (1) Lining the roadways with non-oxidizable material; (2) measures for preventing the spreading of coal dust, and (3) complete re-filling of spaces left after extraction of coal. The lecturer was very optimistic as to the prevention of explosions in connection with coal dust.

Coal Prices

The present high level of coal prices in this country is attributable to a variety of causes working together: limited production, due in some measure to absence of men at the war, and also to the high remuneration permitting of very short hours being worked by the miners being among the chief. So far as the southern centers of population are concerned, especially London, the transport element comes certainly into consideration, and certainly has its influence on the price. The ultimate tendency of the kind of squeeze which the major portion of the community are experiencing, must be in the direction of nationalization of the more important national assets to such an extent as to avoid leaving the country entirely to the direction of a limited number of owners or an organized privileged class of operators.

Peat Fuel

The high price of coal has turned the general attention to other fuels. The possibility of utilizing peat in a water-gas process was originally suggested by Dr. L. Mond, and two plants acting on this principal are actually working in Italy, at Orentano and Codigoro. As described by Prof. Ugo Rossi, these consist of a turret-shaped oven into which the dried and broken peat is thrown. Steam and hot air are admitted by means of jets, and the water in contact with the incandescent mass produces Mond gas, which collects at the top of the oven.

The gas is then subjected to two purifying processes, and is ultimately used for power purposes. The purifying process involves the production of sulphate of ammonia, a peat containing 2.5 per cent of nitrogen yielding about 1½ cwt. of sulphate of ammonia to the ton.

Oil

If the civilization of the future is to follow the oil deposits in the same way as that of the present has adhered (with the usual marked exception) to the coal fields, there is still considerable prospect of improved circumstances for the world's population. While recent additions to the oil areas in Russia can hardly be said to have proved their value so far, the proximity of Roumania and Galicia may be looked to to remedy any existing deficiency. Turkey contains promising districts for investigation, which would be worthy of the attention they will probably ultimately attract. In Africa, Algeria and Egypt have both been the subject of recent exploration in this direction, and a number of wells were completed in the latter. Taking, in fact, the Eastern map of Europe, as well as the adjacent portions of the map of Africa, it appears that civilization, when not already established on the oil country, is satisfactorily progressing toward it.

Copper Cyanide Plating Solutions*

BY DR. MAX C. WEBER

I have chosen as a subject the working of a copper bath, as this is by far the most extensively used and also the most instructive solution.

There are three things which are necessary for the deposition of metal—current, electrode and electrolyte. As the electrolyte or plating solution is the most important, I will confine myself to this item.

The object of employing cyanide solutions for the deposition of copper is to be sought in the fact that in such solutions iron does not replace copper, notwithstanding their places in the electrolytic series, a phenomenon which is due to the complexity of the salt in which the copper is present. The complex salt, which makes this feasible, is the double cyanide or sodium copper cyanide, the anion of which is Na, the cation $CuCy_2$; that is, by the action of the electric current, Na travels toward the cathode, $CuCy_2$ toward the anode. In other words, copper is not present in an ionized stage. Under proper current conditions, *i. e.*, not too high current density and a suitable concentration of the solution, Na is not discharged at the cathode, but reacts with an undissociated part of $NaCuCy_2$, as per the following equation:

$$Na + Na\ CuCy_2 = Cu + 2\ NaCy,$$

thus showing that the deposition of copper is a secondary reaction, and that free cyanide is formed. On the anode, the anion $CuCy_2$ combines with the copper of the electrode, forming cuprous cyanide $CuCy_2 + Cu = 2\ CuCy$.

Cuprous cyanide is insoluble in water, but soluble in cyanide solution, and for this purpose the free cyanide generated at the cathode is required. Supposing we have proper conditions—low current density on both electrodes—enough free cyanide is produced on the cathode in order to keep in solution the cuprous cyanide formed on the anode. As the free cyanide of the cathode is really needed on the anode for dissolving purposes, and as in a still solution the mixing velocity is very slow, stirring and warming of the electrolytic bath would expedite this matter considerably and bring the bath very near to an ideal stage. However, warm and agitated solutions require a more careful observation on account of which these two items have not as yet been paid the attention they actually deserve.

If too high a current density is used on the cathode, not all the Na ions act reducing on the sodium copper cyanide, but are partly discharged, forming sodium hydrate and hydrogen in connection with the water of the bath:

$$Na + H_2O = NaOH + H$$

This reaction accounts for the development of hydrogen or gasing at the cathode. It means that less copper is deposited per ampere hour and not sufficient free cyanide formed in order to keep the anode clean. Therefore, the solution necessitates the addition of sodium cyanide, otherwise the anode becomes coated and the passage of the current is interrupted. Too high a current density on the anode leads to the same result; covering of the electrode with an insulating film of cupri-cupro cyanide.

In regard to current density, it must be borne in mind that warmed and agitated solutions can be worked with a higher current density than cold ones, and that a density of approximately 30 amperes per square foot is quite feasible without yielding a burned and blistered deposit.

Another feature which is quite interesting is the amount of metal deposited per ampere hour. In a copper cyanide solution which contains the metal in the cuprous state, the same number of ampere hours should yield twice as much metal as in an acid bath, providing, of course, all the favorable conditions are prevailing, *i.e.*, a strong solution, warmed and agitated, worked with a minimum amount of free cyanide at a low current density. As, however, common plating solutions are worked on nearly the contrary conditions, the relative amount obtained from a cyanide bath is much lower. How much lower depends entirely on the relative conditions, and only one feature should be emphasized, which has been mentioned above: that the more hydrogen develops on the cathode, so much lower is the percentage of the metal deposited per ampere hour. A low current density results in a high weight of the metal deposited per ampere hour, while the deposition is slow. A high current density yields a lower weight proportionately per ampere hour, but consuming less time for a certain weight of metal deposited, resulting in a greater deposition of metal per hour.

Furthermore, cyanide solutions yield a finer, more homogeneous texture and brighter metal film than the acid baths on account of the secondary copper deposition and because hydrogen may develop more freely on the cathode in such a solution without fear of burning or blistering the deposit.

These few remarks give an idea how complicated the reactions in a plating solution are, and that it requires skill and experience to procure a satisfactory deposit.

The first part of this paper has shown that the constituent which is essential in a copper cyanide bath is the double salt, sodium copper cyanide, consisting of copper cyanide and sodium cyanide, which is easily formed by adding the necessary amounts of each chemical to water. A high-grade sodium cyanide has been obtainable for quite a number of years, but copper cyanide could only be procured at prices which made its use prohibitive for technical purposes.

For this reason many salts—one might call them subterfuges—have been used which were intended to substitute copper cyanide and form the same when brought together with cyanide solution. One should bear in mind that whatever copper salt is brought together with cyanide solution, the final compound is the double salt, sodium copper cyanide. Another fact which should not be lost sight of is that one chemical can replace another only to the extent of the requisite elements, and that by the reaction of two such salts, always a by-product is formed which contaminates the compound desired.

This is the case with the copper cyanide. Copper carbonate, copper sulphate, copper acetate, cupri-cupro sulphite have been employed in order to form copper cyanide in connection with sodium cyanide and water. That by these reactions an inert by-product consisting of sodium sulphate or sodium sulphite or sodium acetate or sodium carbonate is formed to a high percentage every one was aware of, but took it for granted as the product necessary, *i.e.*, copper cyanide was not obtainable commercially.

When using copper carbonate, which is really basic copper sulphate containing a small percentage of carbonate, according to the temperature at which it is precipitated, approximately one-half pound of inert matter is formed for every pound of copper carbonate, being composed of sulphates and carbonates. By the use of copper acetate, or cupri-cupro sulphite this inert matter is still further increased, and for each pound of the compounds used, from nine to ten ounces inert salts are produced. These salts accumulate in the bath more and more with every addition of the respective copper salt, and finally yield such a dense solution, which being overloaded with these waste compounds cannot be worked

*A paper presented before the Lewis Institute, Chicago, Ill.

in a satisfactory manner any longer, the plated articles being blistered and the solutions are of necessity discarded.

The reason for this is that a bath of this kind has a relatively low metal concentration and a much higher one of the inert salts. As a rule, the electric current deposits the metal easiest to discharge, which in this case is the alkali metal. Therefore, as the current density increases an excess of hydrogen is generated, which causes burning, and the current output drops considerably.

After considering this crude method of forming copper cyanide one should remember that the copper in a cyanide plating solution is in the cupro stage, while copper carbonate, copper sulphate, copper acetate are cupri salts, and cupri-cupro sulphite is a mixture of both. This means these salts must be first reduced to the cupro state before they are fit for plating. This reduction is executed at the cost of the sodium cyanide which is actually intended for bringing the copper metal into solution only. Further, neutral copper salts as copper acetate, copper sulphate and cupri sulphite, when brought in contact with cyanide solutions, form cupri cyanide first, which, being an unstable compound, decomposes into cupro cyanide and cyanogen, which latter escapes into the air, and on account of its highly poisonous character is most detrimental to the health of the plater.

Taking into consideration all the disadvantages resulting from the present method for producing a plating solution, every progressive plater should greet with joy the fact that a chemically pure cupro cyanide is now on the market at a price making its use more economical than that of any other copper salt which has been accomplished by new manufacturing methods worked out by the author of this article.

Cupro cyanide contains nothing but the ingredients necessary in a plating solution—copper and cyanogen—so that by dissolving it in cyanide solution no inert, unnecessary products are added. This enables the plater to have perfect control of his solutions at all times, as whenever metal is needed he adds it in the form of copper cyanide, and, when cyanide is needed, sodium cyanide, thus simplifying matters. On account of its high percentage of metal—it contains 70 per cent pure copper, the rest being cyanogen—solutions highly concentrated in metal can be worked at a relatively low specific gravity. This is a further advantage, as a bath low in density is much more easily controlled than a very concentrated one.

Copper cyanide being a cupro salt, does not consume any cyanide in order to be transferred to the cupro stage, and because of its being a cyanide itself it requires less sodium cyanide than any other copper salt to yield the double salt sodium copper cyanide, the essential constituent of a plating solution. This fact points out a more economical method for producing a plating solution. In other words, it saves money. When one buys a metal salt for plating one should not forget that it is not the price of the metal in the salt itself which constitutes the economy of the salt, but the price at which the metal is put into solution as a double cyanide. It is this economy of the copper cyanide combined with its high technical qualities which makes copper cyanide superior to any other plating salt.

The figures in Table I give a comparison of plating solutions produced with different copper salts and are the results of actual tests. The metal contents of the solutions are the same in Table I.

After continuous operations for two hours it was found that while the solution made up with copper cyanide remained almost constant—that is, the relative proportions of metal and cyanide were practically the same—the solution made up with the other salts became unbalanced. The anodes coating over requiring further additions of cyanide, showing once more that solutions made up with chemically pure copper cyanide gave maximum efficiency.

Table I

Copper cyanide, 70 per cent copper:		
100 lbs. copper cyanide at 42c. per lb.	$42.00	
100 lbs. sodium cyanide, 129 per cent, at 22c. per lb.	22.00	$64.00
Copper carbonate, 50 per cent copper:		
140 lbs. copper carbonate at 14c. per lb.	$19.60	
239 lbs. sodium cyanide, 129 per cent, at 22c. per lb	52.58	$72.18
Cupri-Cupro sulphite, termed red copper compound—40 per cent copper:		
175 lbs. red copper compound at 30c. per lb.	$52.50	
160 lbs. sodium cyanide, 129 per cent, at 22c. per lb.	35.20	$87.70
Copper acetate, 31 per cent copper:		
220 lbs. copper acetate at 25c. per lb.	$44.00	
193 lbs. sodium cyanide, 129 per cent, at 22c. per lb.	42.46	$86.46

As so-called copper carbonate was the most extensively used, I gave this solution special attention and found, after considerable experimenting, that in order to obtain a solution with sufficient free cyanide to obtain a fairly balanced solution the following proportions were necessary:

140 lbs. copper carbonate at 14c. per lb.	$19.60	
280 lbs. sodium cyanide, 129 per cent., at 22c. per lb.	61.60	
		$81.20

These comparative figures vindicate once more one of the most important rules in chemistry—that pure materials not only give the greatest efficiency, but are the most economical.

In the present time, which is distinguished by the endeavor to obtain an end as simply and as economically as possible, where everything is standardized in order to obtain the best results at the lowest cost, no farsighted man can dispute the fact that copper cyanide brings this desired standardization to the plating industry which means utmost economy and high results.

Blowers and Fans.—The Clarage Foundry & Mfg. Co. of Kalamazoo, Mich., has recently published a catalog describing Clarage type C.I., cast-iron volume blowers. These fans are built in four sizes, 5, 6, 7 and 9, and the number in each case is the same as the diameter in inches in the suction or outlet connection. The housing or fan case is cast in one piece, and is supported by cast-iron side plates. These plates are larger than the fan wheel, and by merely taking out eight cap screws and removing the plate the wheel may be withdrawn from the housing. This same feature makes these fans adjustable and reversible, as any one of seven different directions of discharge may be secured, and the arm supporting the bearing may be placed on either side of the fan. Although furnished regularly as single inlet exhaust fans with a collar for the suction pipe or intake side it is possible by removing the collar and plate to use these fans or blowers having two inlets, and thus obtain the resulting high efficiency. The special dust-proof, oil-tight, enclosed bearings are features of importance in dusty installations, and the large supply of oil assures a cool running machine. To invert the fans the only change necessary is to interchange the positions of the oil supply pipe and the plug in the bearing. The type C.I. fans, as single-inlet exhausters, may be used to remove smoke, chemical vapors, or fumes from forge fires, stoves, ranges, vats or kettles, exhausting air in small ventilating installations for toilet rooms, telephone booths, etc., or they may be used to convey light material, such as removing dust from emery wheels, or tumbling barrels or shavings from wood-working machines. As double inlet blowers the type C.I. fans furnish blast for forge-draft fans for small boiler plants.

Refractories of the Rocky Mountain Region, and Some of Their Products

BY J. C. BAILAR

Before using a new piece of chemical porcelain ware the chemist has long been accustomed to remove a stamp bearing the word "Germany," and coupled with this habit of years has come the fixed belief in the minds of many people that such ware cannot be made in the United States. The same idea once prevailed with regard to fire-clay goods. The first smelters in the Rocky Mountain region used fire-brick made in England; that assayers also imported muffles, crucibles and scorifiers. It is possible that some American ware was used, but where the fire was hottest no brick was used that did not bear the then magic word "Battersea." Fortunately for the mining industry of this region, the first smelters were erected near a deposit of excellent fire-clay. This deposit marks the eastern boundary of the Rocky Mountains in Colorado and has been opened

FIG. 1—HEROLD CHINA AND POTTERY CO., GOLDEN, COLO.

in many places for a distance of approximately 250 miles. It is accompanied by large bodies of shale and plastic clay suitable for building brick, terra cotta, roofing tile, sewer pipe and the cheaper grades of pottery. In the nearby hills are found quartz and feldspar in abundance. There is enough of each of these to supply raw material for ceramic industries for several generations.

Superior Quality of the Fire-Clay

Tests made by the United States Geological Survey and others show the fire-clay to be one of the best known; but fifty years of practical use had already proved that. The chemical characteristics of some of the clays are shown in Table I. Numbers 1, 2, 3 and 4 are Golden fire-clays; No. 5 is a red-burning plastic clay from Golden, and No. 6 represents an average of fifty paving-brick shales. The analyses are from sources of undoubted reliability.

TABLE I

Analyses of Colorado Clays and Shales

Number	1	2	3	4	5	6
SiO_2	50.35	45.99	46.61	56.41	60.60	56.00
Al_2O_3	34.44	36.94	37.20	26.37	18.86	22.50
FeO	0.75	0.75	0.15	0.00	6.70	6.70
MgO	trace	0.36	0.25	0.20	1.50	1.40
CaO	0.00	0.23	0.44	0.29	2.70	1.20
Na_2O	0.10	0.45	1.23	1.55	....	3.70
K_2O	0.48	0.48				
Ignition loss	13.88	14.13	13.65	14.66	9.32	7.00

The fire-brick made from the clay deposits in this region probably were produced in Golden, Colorado, in the early sixties. They were molded by hand and reshaped by means of a hand press. This method has not been entirely abandoned, though machines are now used for the greater part of the work.

Early in its history the brick industry was enlarged to include the manufacture of assayers' supplies. This department of the work has grown until the Colorado-made assay crucible is known not only from Klondyke to Cape Horn, but has crossed the ocean seeking wider fields of usefulness. Certainly the name "Battersea," once so potent in the assayer's mind, has taken its proper place among the historical relics in Colorado. At the present time two companies are engaged in the manufacture of assay goods on a large scale. The Denver Fire Clay Company and the Mine & Smelter Supply Company both have factories in Denver, bringing the clays from the beds at Golden. The excellence of the products arises, of course, not only from the chemical nature of the clay, but from its physical characteristics as well. And added to these natural advantages in the raw material must be credited the long and expensive experimentation that the producers have conducted in order to determine the proper mixtures, methods of handling, tempering, molding and burning. These latter constitute the secrets of the trade, which are closely guarded in the clay-working industries.

Good sewer pipe and pottery also are being made from the Golden clays, several Denver firms being engaged in this line of work.

Fire-Proof Porcelain Ware

It has long been known that fire-proof goods of a finer grade than bricks and crucibles could be made from the Golden clays. In the fall of 1909 Mr. John J. Herold went to Golden to investigate the possibilities of making cooking utensils. While carrying on these investigations, Mr. Herold was compelled to make ornamental ware to pay expenses, and for nearly a year he was the only workman in his plant. Finally, however, he succeeded in interesting local capital and the Herold China & Pottery Company was organized, with Mr. Adolph Coors, president, and Mr. Adolph Coors, Jr., manager. The factory was greatly enlarged, as shown in Fig. 1, and an additional kiln has been built since the picture was taken. At present fifty people are employed.

About the time the company was organized a few casseroles and evaporating dishes were made and put to practical use in chemical laboratories with fairly good results. Later, when time could be spared from the regular work of the plant, several small lots were made and tested. Each lot was of a different mixture, and consequently there was no uniformity, each was a separate experiment. Every piece made showed excellent resistance to acids and alkalies, and some of the mixtures withstood alternate heating and cooling remarkably well. In fact some lots were superior to the best imported ware, when the two were used in the laboratory side by side.

Chemical Laboratory Ware

Until recently no chemical ware was made except these experimental lots, as the company devoted all its energies to the manufacture of cooking utensils. Now, however, the line of chemical ware is well established, and includes evaporating dishes, casseroles, porcelain crucibles, spatulas, mortars, glazed and unglazed tubes, and in fact everything that the chemist may require. Some battery cells made for the refinery of the United States mint in Denver last 50 per cent longer than the Royal Berlin cells that had been previously used. These products of the Herold factory have been duly investigated by chemical supply houses which have offered to contract for the entire output. It is understood, however, that the manufacturers prefer not to make such a contract, but sell in the open market. This factory has demonstrated beyond question to the writer that we can produce our own chemical porcelain ware in this country, and it does not require an optimist to predict that, with reasonable economic conditions, the stamp "Made

in Germany," so common on chemical porcelain, will gradually disappear.

Enameled Brick

These notes on the manufacture of refractories in the Rocky Mountain region would not be complete without mention of the product of the Sanitary Brick Company, of Golden. This company makes a high-grade enameled brick for both interior and exterior work. The process of manufacture is very different from the one generally used. The bricks are made by the stiff-mud process, and by an ingenious device the enamel is put on by the same machine. When somewhat dry, the enameled face is dipped into the glaze, and when the drying is complete the bricks are burned not in saggers or muffle kilns, but in common down-draft kilns such as are used in the manufacture of building brick. The enamel is about ⅛ in. thick and is united to the body just as the glaze is united to a dinner plate. No line of cleavage can be found between the body and enamel when the brick is broken. It is scarcely necessary to say that to make and enamel ware in one operation, glaze the ware while green and complete it in one burn is not the usual procedure. These bricks will be used for part of the interior finish of the new Union Depot and Post Office now being built in Denver.

Golden, Colo.

Regulation of Electrotyping Solutions

The Bureau of Standards has started an investigation of electrotyping problems and the first result is Circular No. 52, just issued and entitled "Regulation of Electrotyping Solutions." The Bureau is not yet able to make definite recommendations regarding the best composition of solutions to be employed for any given method of operation for either copper or nickel electrotyping.

The circular first discusses the expression of the density of a solution either in degrees Beaume or by its specific gravity and gives two conversion tables. As to the composition of solutions it is said that in view of the almost universal use of the metric system in chemical analysis and other scientific work, preference will be given to the metric system in expressing the composition of the solutions. Since, however, the ordinary United States units are generally employed in electrotyping and similar commercial work, the values will also be expressed in such units. In making such calculations the following values and equivalents will be employed:

One avoirdupois pound = 454 grams.
One avoirdupois ounce = 28.35 grams.
One United States liquid gallon = 231 cu. in.
One United States liquid gallon = 3.785 liters.
One liter = 1000 cc.
One liter of water weighs 1000 grams.

From these values the following simple rules may be derived:

(*a*) To determine the approximate capacity of the vats in gallons, divide the cubical contents in cubic inches (up to the height of the solution) by 231.

(*b*) To convert grams per liter (g/l) to ounces per gallon (oz./gal.), multiply by 0.134; or divide by 7.5. Thus 50 g/l is equal to $50 \times 0.134 = 6.7$ oz./gal.

(*c*) To convert grams per liter to percentage by weight divide the grams per liter by ten times the specific gravity of the solution. Thus for a solution with a specific gravity of 1.15, 50 g/l is equal to

$$\frac{50}{10 \times 1.15} = \frac{50}{11.5} = 4.3 \text{ per cent.}$$

The portion of the circular which deals with regulation of the copper solution we give in full as follows.

Copper Solutions

1—GENERAL INFORMATION

The solutions usually employed for copper electrotyping contain, in addition to water, only copper sulphate and sulphuric acid. Since these substances and also the anode copper are usually fairly pure, there is no marked tendency for impurities to accumulate in the solution. The principal changes taking place in the composition of such solutions are due to two causes, (1) mechanical loss of the solution adhering to the "cases" (cathodes) when removed from the vats, and (2) solution of a greater amount of copper from the anodes than is deposited on the cathodes. The first factor would in itself

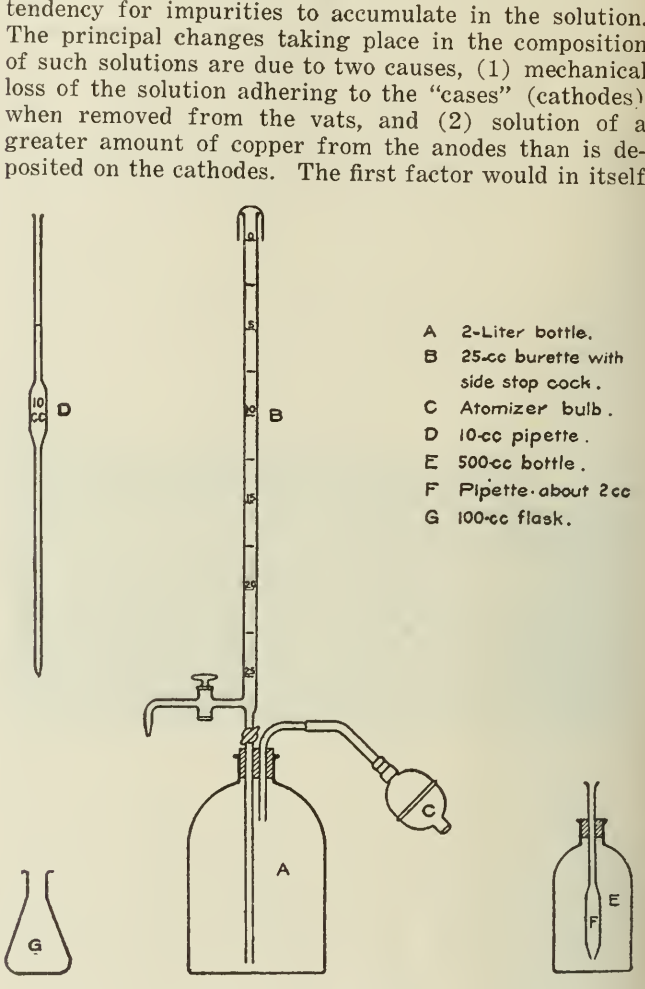

FIG. 1—APPARATUS FOR TESTING ACIDITY

cause a decrease in the density of the solutions, if, as is customary, the level of the latter is maintained approximately constant. (Water is added to the vats at intervals in order to replace that lost by evaporation.) The second action will cause a decrease in the acidity and an increase in the density of the solutions, owing to a consumption of sulphuric acid with the production of a corresponding amount of copper sulphate. In all cases thus far observed the latter effect is predominant. The exact causes of this consumption of acid and the best methods of reducing or eliminating it are now the subjects of investigation by the bureau.

In general it is necessary at intervals to determine and correct the composition of the solutions. The mere determination of the density of such solutions, whether with Beaume or specific-gravity hydrometer, is not sufficient to fix their composition. If, however, the density of the solutions and also the amount of free sulphuric acid present are determined, the composition is fixed. Thus, for example, a solution with a specific gravity of 1.16 (20 deg. Beaume) and containing 45 grams per liter (6 oz. per gallon) of free sulphuric acid has a perfectly definite and reproducible composition. The above figures do not, to be sure, indicate the amount of copper sulphate present in such a solution, but this is of no consequence to an electrotyper except when he is

preparing a new solution. For such cases tables showing the amount of copper sulphate required to produce solutions of any desired density, with any specified acid content, would be desirable, and will probably be prepared.

The bureau is not yet able to recommend any composition of the solutions as best adapted to any given conditions of operation. In various commercial solutions thus far tested the specific gravity ranges from 1.12 (15.5 deg. Beaume) to 1.20 (24.2 deg. Beaume) and the acidity from 25 g/l (3.3 oz./gal.) to 90 g/l (12 oz./gal.). In general the lower the voltage employed the more acid is required to produce a given current strength and rate of deposition, and vice versa. For the present, each operator should find a composition of solution which will give him satisfactory results under his conditions, and maintain it as nearly constant as possible by adjusting the density and acidity of the solutions at regular intervals (e.g., once a week) by the methods described in the following sections.

2—DENSITY

Before testing the solutions they should always be adjusted to the normal level of the vats by the addition of water if necessary, and thoroughly mixed. The hydrometer should always be read in the same way, preferably by floating it in a glass jar or cylinder containing the solution. By placing the eye slightly below the level of the solution, and then gradually raising the eye, the surface, first seen as an ellipse, becomes a straight line, the intersection of which with the hydrometer scale should be taken as the reading of the hydrometer. For practical purposes, and especially for comparison, the readings will usually be sufficiently accurate if made by observing the hydrometer scale above the surface of the liquid. The density should always be taken at approximately the same temperature, preferably 60 deg. F.

Having determined the density of the solution (which will usually be found to be higher than is desired), it may be adjusted to the desired density by the following method, based on the assumption that the excess density of the solution (above that of water) is approximately proportional to the content of the dissolved substances.

(*a*) *Specific Gravity.*—If a specific-gravity hydrometer is employed, divide the difference between the observed and desired specific gravities by the difference between the observed specific gravity and the specific gravity of water, which is 1.000. The result is the percentage of the solution which should be replaced with water.

EXAMPLE

Observed sp. gr.	1.179	Observed sp. gr.	1.179
Desired sp. gr.	1.160	Sp. gr. of water	1.000
Difference	.019	Difference	.179

$$\frac{0.019}{0.179} \text{ or } \frac{19}{179} = 10.6 \text{ per cent.}$$

Therefore, replace with water 10.6 per cent of the solution, or 10.6 gal. for every 100 gal. in the vat.

(*b*) *Beaume.*—If a Beaume hydrometer is used, the calculations are even simpler, and for practical purposes are sufficiently accurate. In this case we simply divide the difference between the observed and desired density, in degrees Beaume, by the observed degrees Beaume, to obtain the percentage of the solution to be replaced with water.[1]

Example

	Deg.
Observed degrees Beaume	22
Desired degrees Beaume	20
Difference	2

$$\frac{2^\circ}{22^\circ} = \frac{1}{11} = 9.1 \text{ per cent}$$

3—DETERMINATION OF ACIDITY

(*a*) *Principle.*—The amount of free sulphuric acid in the solution is determined by measuring the volume of an alkali solution of known strength which is required to neutralize the acid present in a measured volume of the solution. An indicator (methyl orange) is added to the solution in order to show, by its change in color, when all the acid is neutralized by the alkali. The method as applied to such solutions is not original, having been published by Wogrinz[2] in 1913. Even before that time it was used in a few electrotyping establishments in this country.[3]

(*b*) *Apparatus.*—The only essential pieces of apparatus for making this test are a pipette to measure the copper sulphate solution, a burette to measure the standard alkali, and a few bottles. Fig. 1 illustrates a form of apparatus that has been found convenient in this work. Doubtless many other forms of reservoir burettes will be found equally suitable. This apparatus and also the necessary solutions can doubtless be secured for a moderate charge from any local chemist or chemical supply house.

(*c*) *Solutions.*—(1) *Alkali.*—A sodium hydroxide (caustic soda) solution of any *known* and convenient strength may be employed. In a preliminary circular of the Bureau a solution prepared of a strength (0.61 normal) equivalent in the titration to 3.0 grams per liter of sulphuric acid was suggested. In view of the greater ease of securing a normal solution of sodium hydroxide the Bureau now recommends the use of a *normal*[4] solution. One cubic centimeter (1 cc) of such a solution will neutralize 0.049 gram of sulphuric acid. If, therefore, a sample of 10 cc (or 1/100 of a liter) of the copper solution be titrated, each cubic centimeter of the sodium hydroxide required is equivalent to 4.9 grams per liter (or for most practical purposes 5 g/l or 0.67 oz./gal.) of sulphuric acid. Solutions of other strength may be employed, provided the calculations be correspondingly changed. Since the sodium hyroxide may change in strength on standing (owing to its attacking the glass of the container) it should either be renewed, or restandardized by a chemist, at intervals of about six months.

(2) *Methyl orange* solution, containing one part of methyl orange in 5000 parts of water, is used as an indicator, i.e., it changes color when all the sulphuric acid is neutralized.

(*d*) *Titration.*—To carry out the titration, measure with a pipette 10 cc of the copper sulphate solution to be tested (after the bath has been adjusted to the desired specific gravity and thoroughly mixed) and run it into a small flask. Add to it about 2 cc of the methyl orange solution. To adjust the sodium hydroxide solution to the zero mark in the burette, turn the center stopcock so that the burette is connected with the stock bottle, and with the bulb pump the solution until it is above the zero mark, and then shut off this stopcock. Next turn the side stopcock and allow the solution to run into any convenient vessel (for waste) until all air is displaced from the side tube and the lower edge of the curved surface of the liquid is just at the zero mark. Now run the sodium hydroxide solution into the copper sulphate solution slowly, with constant shaking, until

[1] Since 22 degrees Beaume = 1.179 sp. gr., and 20 degrees Beaume = 1.160 sp. gr., the results in the above examples by the two methods of calculation should be the same, instead of 10.6 per cent and 9.1 per cent, respectively. The observed difference, which is due to the assumption that the readings of the Beaume scale are proportional to the specific gravity, is negligible in practical work, being equivalent to a difference of only 0.003 in the resultant specific gravity. Whichever instrument is used, there is no advantage in a very accurate adjustment of the density, since this will be somewhat altered by any subsequent addition of sulphuric acid.

[2] Chem. Ztg., 37, p. 869; 1913.

[3] Private communication from Wilson Yerger.

[4] This should not be confused with a *decinormal* solution, which is often used in scientific and technical work.

the violet color of the solution just disappears. If a decided green color or appreciable precipitate appears, too much alkali has been added and a new portion should be titrated.

Note the position of the lower edge of the curve at the end of the titration. After completing the titrations, allow the burette to empty and put a *little* vaseline on the stopcocks.

(*e*) *Calculation.*—To find the number of grams per liter of sulphuric acid in the copper solution, multiply by *five* the number of cubic centimeters of alkali used in the above titration. To find the number of pounds of acid to be added for each 100 gal. in the bath, deduct the amount of sulphuric acid thus found from the prescribed content and multiply the result by 0.83, or practically 5 ÷ 6. (Since 1 gal. is equal to 3.79 liters, or 100 gal. equal 379 liters, we multiply by 379 the number of grams per liter required; and since there are 454 grams in 1 lb., we divide the last result by 454. For practical purposes, therefore, we multiply by 379 ÷ 454 or 0.83.)

For any given capacity of vat the correct factor can be readily determined.

Example.—Suppose 10 cc of the copper solution requires 9 cc of the alkali in the titration. Then the solution contains $9 \times 5 = 45$ grams per liter of acid. If, for example, we desire to have present in the solution 60 grams per liter of acid, it is necessary to add $60 - 45$ or 15 grams of acid for each liter of the solution. For a vat holding 100 gal. we must add 15×0.83 (or $15 \times 5 \div 6$) = 12.5 lb. of acid. Or, if the vat holds, for instance, 180 gal., we use the factor $180 \div 100 \times 0.83 = 1.49$; i.e., we must add $15 \times 1.49 = 22.4$ lb. of acid.

(*f*) *Notes.*—(1) In the above operations and calculations extreme accuracy is not required, since all that can be accomplished is to keep the composition of the solutions approximately constant. The chief value of such tests will be to enable the operator to avoid obtaining defective work, or, in cases where the work may prove defective, to determine immediately whether the composition of the solution or some other condition is at fault.

(2) A permanent record of all titrations and of all changes in or additions to the solutions should be kept. Such records will ultimately furnish valuable information regarding the operation of the bath.

The circular is concluded by some brief non-committal notes on nickel electrotyping solutions.

The **Scientific Specialties Company**, of 17 Madison Avenue, New York City, has perfected arrangements with the C. P. Link Company to act as distributors for the Link water still (described in an article on page 796 of our issue of December, 1914). The Scientific Specialties Company will also act as the agents for a new hard porcelain of Bauscher make with excellent acid, alkali and heat-resisting qualities.

Coal Drier.—The Link-Belt Company has just issued a pamphlet on the Wendell drier in which the drying of washed coal for coking purposes is carried out by centrifugal force in automatic and continuous operation.

The **Chapman Engineering Company**, Mt. Vernon, Ohio, report considerable improvement in the gas producer trade. They have recently received an order from the Irtysh Corporation, London, England, for two 10 ft. Chapman rotary full mechanical producers. These will be installed in their zinc smelter at Ekibastous, Siberia. The New Jersey Zinc Co. have ordered four producers of this same type for their Palmerton, Pa., plant. These producers will gasify anthracite coal.

The Tapalog, a New Multiple Record Pyrometer Recorder

The Wilson-Maeulen Company, 1 East 42nd Street, New York City, has just placed on the market a new pyrometer recorder for multiple records, called the Tapalog, which embodies various radically new and decidedly interesting features.

Fig. 1 shows the tapalog operating in connection with four thermocouples.

Fig. 2 shows how in the tapalog the carriage sup-

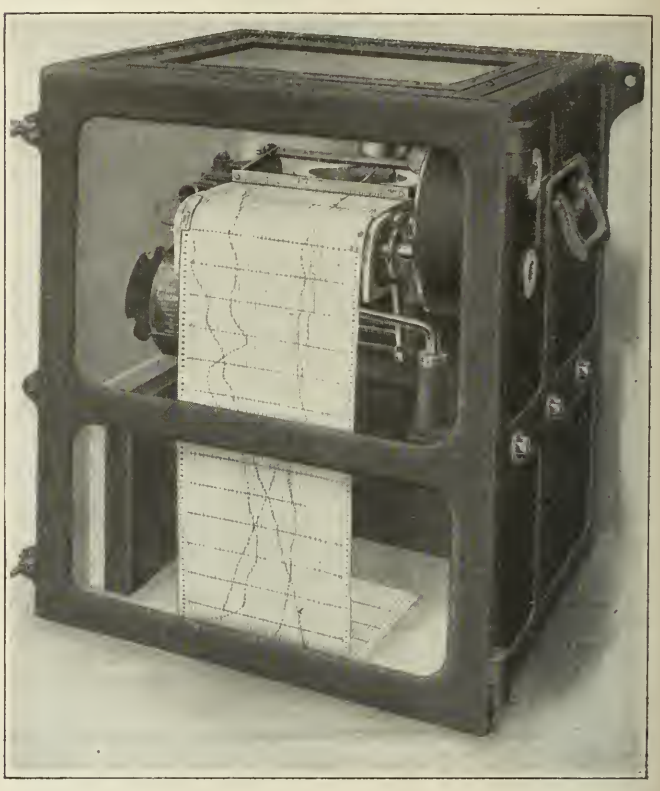

FIG. 1—THE TAPALOG OPERATING IN CONNECTION WITH FOUR THERMOCOUPLES

porting the record materials is lowered for change of paper and ink ribbon.

Fig. 3 shows the tapalog with paper roll and typewriter ribbon removed and discloses the straight edge which is the platen that results in rectangular coordinates for the record paper.

The idea of using a multi-color typewriter ribbon is new, and the idea of having the carriage, containing the ribbon and record paper, pivoted so as to swing down and away from the galvanometer is a great convenience to the operator, as the roll of paper can be taken out and the typewriter ribbon changed without having to carry on these operations in close proximity to the galvanometer.

By a crank motion the pulleys, around which the typewriter ribbon rotates, oscillate back and forth at right angles to the belt-like traverse of the ribbon so that the wear is distributed in somewhat of a sine wave. In addition to this oscillation, there is also the lateral shift, bringing the new color band into position synchronously with the rotation of the switch which connects the tapalog to another thermocouple.

In its simplest form, the tapalog has a single color band and operates with only one thermocouple, but it is generally furnished with the multi-record attachment shown at the left of photograph Fig. 2, and it will then take records of two, three or four thermo-

couples, each in a distinctive color, these colors being red, black, green, and violet.

An electromagnet, which operates the automatic switch, also operates the periodic depression of the boom carrying the indicating scale and which gives the blow that makes the dot and which boom lifts

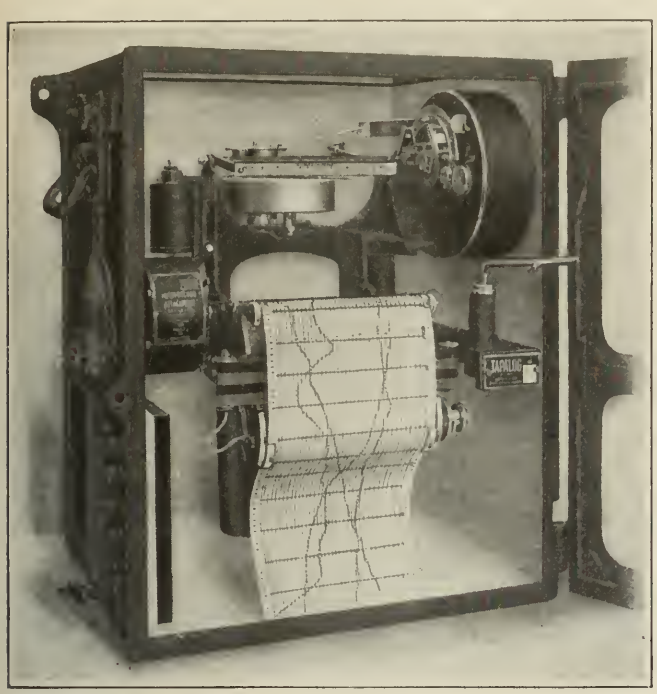

FIG. 2—THE TAPALOG WITH CARRIAGE SUPPORTING RECORD MATERIALS LOWERED FOR CHANGE OF PAPER AND INK RIBBON

slowly, leaving the pointer free to swing to its true position between the time of dotting. One dot is made every twelve seconds.

The clock has practically no work to do other than furnish the time. Actually the chopper boom is over-counterbalanced so that it tends to rise and is held

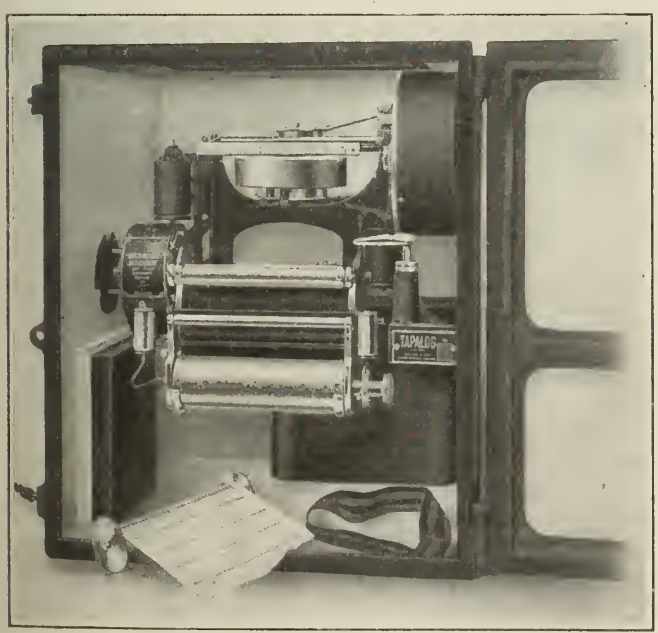

FIG. 3—THE TAPALOG WITH PAPER ROLL AND TYPEWRITER REMOVED, DISCLOSING STRAIT EDGE WHICH IS THE PLATEN THAT RESULTS IN RECTANGULAR CO-ORDINATES FOR THE RECORD PAPER

back by the clock, so that it almost drives the clock but in a way that does not disturb the good timing by the clock. This is a radically new feature in a clock-controlled recording instrument.

There is a convenient zero adjuster, accessible from the front, a start and stop lever for the clock, and a lever on the multi-record attachment enables one to instantly change the multiple recorder to a single-record type operating continuously on one thermocouple.

The instrument is in a metallic dustproof case which is even dustproof at the clock keyholes. All insulating pieces are bakelite instead of fibre or rubber.

The record paper is a good tracing paper, and the record is taken on the under side and is practically as clearly visible on one side as the other. By having the typewriter ribbon on the under side, the record is visible instantly after being made and the pointer never comes in contact with the inking material and stays clean and frictionless. The record is manifestly in shape for blue printing. The width of the record paper is 6 in. and the actual calibration is $5^1/_4$ in., and the advance of the paper is 1 in. an hour.

A two-record instrument, for instance, can be changed to a four-record instrument by the user in less than a minute by simply slipping on a four-color ribbon in place of the two-color ribbon and by making the proper connections at the binding posts on the outside of the case.

While this is a new instrument, quite a number of them are now in service, and they are taking excellent records to the entire satisfaction of the operators. Galvanometers of different sensitivity are to be used in the tapalog for different temperature ranges and different kinds of thermocouples.

The electrical contacts have been given most careful attention in the Tapalog. The contact which closes the battery circuit for operating the automatic switch and the depressing boom is platinum-rhodium on platinum, and the contact is operated by a blow from power furnished by the electromagnet itself and not by the clock; in fact, there are two of these contacts in parallel, and in addition there is provided a rotary double scraping contact, also platinum, so that it is hard to conceive of the possibility of the electric circuit not be properly closed. In the automatic switch the brush contacts are platinum-rhodium sliding over gold wires mounted on the periphery of bakelite disks.

A Flourishing German Smoke Abatement Society

BY JOHN B. C. KERSHAW

The tenth annual report of the Hamburg *Verein für Feuerungsbetrieb und Rauchbekämpfung*, which has recently made its appearance, is like all its predecessors, a valuable and instructive publication. As the Hamburg society is carrying out what is probably the most successful practical work in the cause of smoke abatement in Europe, some account of its organiaztion and activities may prove of interest.

The society was founded in the year 1902 by a group of Hamburg manufacturers, who were convinced that some better system of control of their boiler and heating plant was desirable than the one customary up to that date. Large firms with unlimited resources and a huge coal bill could afford to employ chemical engineers to devote their whole energies and time to the scientific management of the heating and steam raising plant. The smaller power-users in the city were handicapped, however, by the difficulty of obtaining expert control or management of one or two boilers or furnaces, and

as a result of this difficulty the power plant in small factories was left too often entirely in the charge of a fireman or engineer whose scientific knowledge and technical training was quite inadequate to the demands made upon it. Smoke, inefficiency and waste were the natural accompaniments of this state of things, and it was to remedy these that the Hamburg *Verein für Feuerungsbetrieb und Rauchbekämpfung* was founded.

How successful the society has been in its own particular sphere of operations is shown by Fig. 1, which records in diagrammatic form the growth of the society in the various classes of membership and in the number of boilers placed under its charge since its birth, twelve years ago. The apparent set-back met with in 1911 was due to the foundation of a branch society in Helsingfors, Finland, and to the transfer to the register of the new society of some of the members and boilers of the parent organization. It is satisfactory to note that the curves both for membership and for boilers have once again assumed an upward trend, and that on April 1, 1914, the Hamburg society had 500 members and 1744 boilers and other heating installations on its register.

The work of the society is controlled by a committee of seven members, elected annually. The technical and

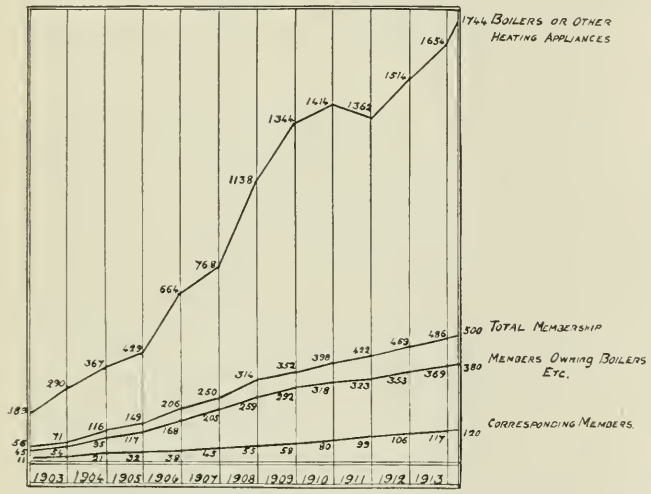

FIG. 1—GROWTH OF THE HAMBURG SOCIETY IN THE PERIOD 1902-1914

scientific work is undertaken by the staff of experts retained by the society for this special purpose. At the date of the last report this staff consisted of a chief engineer, three assistant engineers, five instructors for firemen and three clerks—while for special steam-raising and other trials additional assistance had been employed. The chief engineer attends the committee meetings and takes part in the discussions relating to the work of the society. The funds of the society are drawn from three sources: From the annual subscriptions of its members; from payment for special work and reports for its members; from payments for outside work.

The society is thus entirely self-supporting and its success is dependent upon the value of the return it makes to its members for their contributions and fees.

The objects of the society, as set forth in the rules, are the attainment of the highest possible efficiency from the heating and boiler plants of its members with the least possible emission of smoke. To this end regular examination of these plants and of the methods of working them is undertaken by the expert staff of the society, and suggestions are made for improvements when such are required. The education and control of the firemen in the proper performance of their duties are also undertaken by the firemen-instructors on the staff of the society. Comparative tests of fuel and tests of smoke prevention devices and other appliances of a similar character are also carried out by the expert staff and the results are circulated among the members of the society.

Each boiler or heating plant, when brought under the control of the expert staff of the society, is tested at the earliest possible date, and a written report upon the results of the examination is submitted to the owner. Should the firing have proved inefficient one of the firemen instructors is sent to the works to give practical instruction to the firemen employed there, and tests of

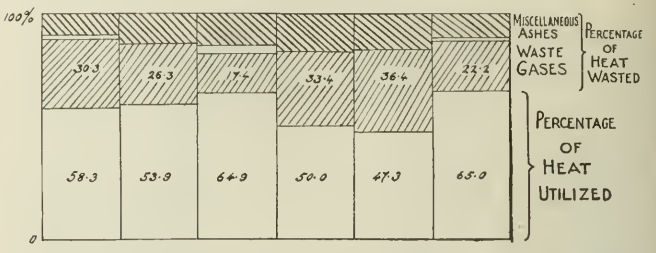

FIG. 2—RESULTS OF THE FIRST TRIALS BEFORE SPECIAL TRAINING OF STOKER

the plant are made at intervals until this fault is remedied. Defects in design are similarly dealt with.

The annual subscription to the society for members without any boiler or heating plant (fördernde mitgliedër) is 20 marks ($5). Members having boilers or furnaces which they desire to place under the control of the experts of the society pay a further 20 marks ($5) annually for each boiler or furnace.

The extra charges for tests and reports are based upon the time spent upon them and the number of experts employed. Engineers are charged for at the rate of 20 marks ($5) per day and firemen-instructors at 5 marks ($1.25) per day. Special reports upon patented appliances are charged for at the customary rates; members receive a special discount of 30 per cent on these as compared with outsiders.

Turning now to a consideration of the practical results of the work carried on by the society, as recorded in the past annual reports, we find that great stress is laid upon the improvements in efficiency due to the training of the stokers in the proper performance of their duties and figures are given in every report showing

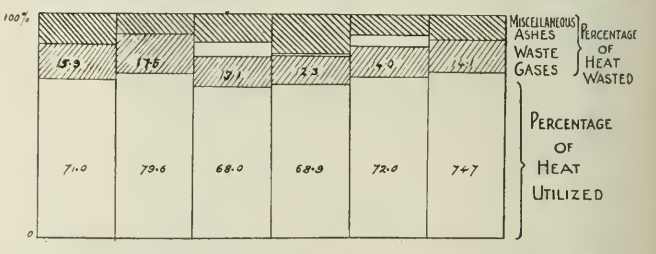

FIG. 3—RESULTS OF THE FIRST TRIALS AFTER SPECIAL TRAINING OF STOKER

gains in efficiency varying from 10 per cent to 20 per cent from this one cause alone. As examples of the gains which have followed from the society's control of boiler plants the two diagrams, Figs. 2 and 3 (taken from the 1912 report), are interesting, since they show in graphic form the results of tests on the same boilers before and after the engineers of the society had taken charge of the respective plants.

The heat loss in chimney gases, ashes, etc., is here seen to have varied between 35 per cent and 53 per cent when the boilers were working under the normal conditions, i.e., in charge of their usual stokers; while after

the society's expert staff had taken control the total heat losses were reduced to between 21 per cent and 32 per cent. The best efficiency recorded in these diagrams is that of No. 2 installation, with 79.6 per cent of the heat value of the fuel utilized in steam-raising, compared with only 59.9 per cent utilized before the transfer of the boiler plant to the company's charge. This represents a gain of 19.7 per cent in efficiency and a saving of 20 per cent on the coal bill.

It is most important to note that the society does not merely test each boiler or furnace plant once and then leave the stokers or engineers to their own devices again. The plant is visited, inspected and tested at regular intervals of time and by systematic instruction and oversight of the regular firemen at their work, an attempt is made to render permanent the gains shown by the first run under more scientific conditions. The staff of "instructors for firemen" have an important rôle to fill in this regular work of the society, for when any plant is not producing the results expected from it one or more of these expert firemen is sent and instruction and advice are given on the spot to the regular fireman of the plant. When necessary the expert fireman takes sole charge of the boilers and fires for an hour or two while the regular fireman looks on. This undoubtedly is the best way to train firemen in the practical side of their duties, for though evening classes and lectures have their value and place they can never be a satisfactory substitute for practical oral instruction given on the firing-plate of the boilers by a man who can handle a shovel as well as he can explain the chemistry of combustion.

Enough has been said above to indicate the general lines and methods of the Hamburg society's work and the results achieved and a small space may be devoted now to the special investigations referred to in the last report. For the expert staff of the society in addition to its regular control of the steam-raising and heating plant of its members is always carrying on special tests of new forms of grate or of some other accessory of boiler plant. Latterly a very large number of comparative tests have been made with mechanical stokers of both the "sprinkler" and "coker" types. The results of these special tests are included in the annual reports, and a complete set of past reports of the Hamburg society is therefore a most valuable addition to the reference library of all consulting engineers who are specially interested in boilers and steam-raising plant.

The special investigations that are dealt with in the tenth report are the following:

1. Trials and tests with mechanical stokers: (*a*) Sprinkler type; Axer; Dingler, "Man," Weck, Mückner, Seyboth. (*b*) Chain-grate stokers. Babcock & Wilcox, "Bamag," "Man," Steinmüller.
2. Trials and tests with regulators of secondary air supply to hand-fired boilers.
3. Tests of water-cooled hollow bar. German "Prometheus" grate.
4. Ships boilers and their methods of firing; cylindrical boilers.
5. Artificial draft for boilers.
6. Domestic heating appliances.
7. Results of fuel-tests.

With reference to the last subject in this list it may be stated that for the past three years the Hamburg society has taken considerable interest in the movement for purchasing fuel on a more scientific basis and that it has appointed Dr. Aufhauser, of the Thermo-Chemische Prüfungs-und Versuchs-Anstalt, in Hamburg, official fuel analyst for the society. A large number of members of the society take advantage of this arrangement to have regular samples taken and tested of their fuel supplies, and the last report of the Verein contains many hundreds of test results of the fuel samples taken in 1913 and in preceding years. As the fuels are classified under the county or district from which they come and more than one-half the tests refer to English and Scotch shipping coals, this appendix to the report is of more than local interest and value.

Further Notes on the Refractory Properties of Zirconia

BY H. CONRAD MEYER

The remarkable heat-resisting properties of zirconia have been known for many years, but it is only within the last few months that serious attention has been given in America to its possibilities in metallurgy and furnace technology. The reader is referred to an article appearing in this journal for a brief history and description of zirconia.[1] Heretofore, zirconia has been considered one of the rare oxides and hence of limited application. It is now being supplied, however, in commercial quantities, and in many instances, is now being used on an industrial scale. A free exchange of ideas among many investigators has rapidly advanced the technology of zirconia, and the writer hopes that the preliminary data here given may be of value to all those now working on this new refractory body. Many of the investigations have been carried out by the author, and numerous independent reports have been secured from private sources, for which due credit is given.

Analysis of Natural Zirconia

In the investigation of refractory substances, a complete chemical analysis is often found of value. The presence of alkalies, silica and iron oxide often plays an important part in the behavior of the material when subjected to high temperatures. The mean of three analyses of an average sample of natural zirconia is given herewith:

ZrO_2	84.1
SiO_2	7.74
Fe_2O_3	3.10
TiO_2	1.21
Al_2O_3	.66
Loss on ignition	2.72
	99.53

It will be noted from the above, that the only two oxides present which would be likely to cause a lowering of the melting point of the zirconium oxide, are silica and ferric oxide. The 1.21 per cent of titanium oxide present, may or may not exert a fluxing action at high temperatures, but the practice seems to be, in manufacturing most fire brick and refractory ware, to disregard this oxide entirely. The ignition loss consists mainly of moisture with a small percentage of organic matter.

Heat Tests on Zirconia[2]

An ore containing 84 per cent Zro_2, ground to 100 mesh and mixed with H_2O, molded easily into cones which kept their shape when burnt with little warpage or shrinkage to about the temperature of cone 35 (1830° C.). These tests on cooling show a slightly vitrified material with a smooth and fine-grained surface.

Zirconia mixed with a 5 and 15 per cent mixture of Bens Creek clay, in view of finding a suitable bonding material, and heated to a temperature over cone 31 (1750° C.), shows the 15 per cent tests to be in fair

[1] *Met. & Chem. Eng.*, Vol. 12, No. 12, page 791, Dec., 1914.
[2] Data taken from the results of three or more tests on separate mixtures by G. T. Stowe.

shape, that is, slightly vitrified, cracked and coarser grained, while the 5 per cent test is in good shape with a fine finish and very little shrinkage or warpage. A mixture of 5 and 15 per cent Warrior Ridge clay with the zirconia and heated to the temperature of about cone 32 (1770° C.) shows the 5 per cent mixture to be in excellent shape with a clean cone standing at the end of the test. The 15 per cent mixture does not hold up quite as well at the same heat.

A mixture consisting of 98 per cent 100-mesh zirconia and 2 per cent slacked lime worked into a plastic form with H_2O, showed a fusion point of about cone 30 (1730° C.). Further, this cone lost its shape by warping at least five cones before the mixtures with clay.

The mixtures on a whole were easily molded. The pure zirconia test cones seemed to have some plastic properties and held together very well, making a clean and sharp-edged cone.

The burnt product seems to be a likely refractory material, granting that the higher heat and flux standing properties make up for the advance in the cost of manufacturing the material in comparison with other refractory wares. The vitrified samples show a very hard and seemingly strong ware.

Of all the tests made, the 5 per cent mixture of Warrior Ridge clay with the zirconia seems to make the best bond; produces the best appearing samples before and after burning, the pure zirconia tests excepted, and those only as to heat tests.

Fire Shrinkage[3]

Small briquets of the following were carefully made, measuring 36 x 20 x 5 mm. These when thoroughly dried, were burnt at a temperature of approximately 1427° C. in a No. 2 muffle furnace supplied by the American Gas Furnace Company.

No. 1. Pure zirconium oxide (99 per cent ZrO_2).
No. 2. Wet ground zirconia (84 per cent ZrO_2).
No. 3. Zirconia (95 per cent ZrO_2).
No. 4. 93 grams of No. 3, and 7 grams Dry Branch kaolin.
No. 5. 60 grams zirconia, 80 mesh (84 per cent ZrO_2) and 40 grams wet ground zirconia.

Linear shrinkage at 2600 deg. F.:

No. 1..... 9 per cent.
No. 2..... 9 per cent.
No. 3..... 9 per cent.
No. 4.....12 per cent.
No. 5..... 3 per cent.

Briquet No. 1, made from pure zirconium oxide, analyzing about 99 per cent ZrO_2, yielded a sticky mass on mixing with water and was quite soft after drying. After burning No. 1 was still in a soft condition and could be readily scratched with the nail.

Briquet No. 2 consisted of natural zirconia carrying about 84 per cent ZrO_2, corresponding to the analysis given above. As indicated, this material was wet ground in a ball mill and thus reduced to an extremely fine state of subdivision. It was readily molded into shape. Firing rendered the material extremely dense and of a flint-like hardness. Several briquets were heated to redness and one end plunged into a beaker of water. This quenching test apparently left the material unaffected, as no cracks were developed.

Briquet No. 3 was made from 95 per cent zirconium oxide. This 95 per cent product was prepared on a small scale from the natural or 84 per cent zirconia. Most of the silica and nearly all of the iron were removed by this refining, which yielded a light gray product. After firing, the briquets presented a very dense structure and were extremely hard.

[3]Author's tests.

Briquet No. 4 shows the bad effect of even a small percentage of a very refractory china clay. Dry Branch kaolin is a pure white, washed clay, having a fusing point above 1790 deg. C.

Briquet No. 5 was made from a mixture of 60 grams coarse zirconia (material passing through an 80 mesh screen) and 40 grams water-ground zirconia, or material similar to No. 2. It will be noted that the shrinkage in this case was extremely low. The briquet, after firing, presented a rather coarse, porous texture, but possessed considerable tensile strength.

Whether these shrinkage figures would be greater at higher temperatures, it is difficult to say.

Selection of a Binder

The proper choice of a binder is a very important consideration, as the fusing point of the zirconia is influenced largely by the substance added as a bond. Phosphoric acid, sodium silicate, and lime were tried, but with indifferent success, and in many cases it was clearly apparent that such bonds were positively detrimental.

The following data were secured from a private source.[4] The tests were made in the form of small briquets measuring 1¼ x 1¼ x 4 in. in a steel mold. The material was rammed in place with considerable pressure. Five such tests were made as follows:

(1) Zirconia powder, bonded by 26.5 deg. Bé$MgCl_2$ solution (concentrated from salt bittern). Mixed to consistency of a stiff mud and rammed. Dried 5 days—100 deg. C. Dried 8 hours—150 deg. C. Heated gradually to bright red and exposed to temperature of 1600 deg. C in an electric arc furnace for two hours. The sample showed no fusion; corners sharp and hard; scratch glass; shrinkage slight; FeO and Fe adhere in molten condition; FeO showed corrosion; very dense; difficult to crack with bricklayer's hammer.

(2) Zirconia powder, 50 per cent; dead-burnt magnesia (electrically dead-burnt), 50 per cent; bonded by 26.5 deg. Bé $MgCl_2$ solution and mixed to hard, stiff mud and rammed. Dried same as 1. Heated to same temperature and for same time as 1. Fused to spongy mass, dark color. The fusion was evidently caused by iron oxide and silica.

(3) Zirconia powder, 10 per cent; dead-burnt magnesia, 88 per cent; 26.5 deg. Bé $MgCl_2$ solution, 2 per cent. Mixed to stiff mud and rammed. Dried and heated same as for 1. Hard, dense, compact brick; sharp, hard corners; positively no fusion; showed no corrosion by FeO; light brown color.

(4) Zirconia powder; bonded by 30 deg. Bé Na_2SiO_3 solution to form stiff mud and rammed. Dried and heated same as 1. No fusion; extremely hard, dense; interior appeared denser than exterior; slight crack in interior, probably due to moisture.

(5) Zirconia powder; bonded by small amount of water in form of vapor, mixed to stiff mud and rammed. Dried and heated same as for 1. Compares to properties of 1. Showed same FeO corrosion.

With the exception of 2, which fused, the samples showed:

(1) General corrosion by FeO in spots.
(2) Slight shrinkage.
(3) Withstood temperature changes from 500 deg. C. to 1600 deg. C., without any cracking or spalling.
(4) No contortion or deformation at high temperature.
(5) Precaution necessary in choosing suitable binder, and also care to be used in mixing with other refractory substances containing impurities as FeO, SiO_2, etc.

[4]R. C. Gosrow.

(6) Zirconia can be used equally with magnesia, and with less cost for linings, etc.

The results secured by Mr. Gosrow under test No. 3 appeared promising enough to warrant further investigation along this line. Preliminary tests indicate that magnesium chloride would be objectionable on a commercial scale. Hence, another binder was sought and ultimately found in water-ground zirconia. It was further considered that the dead-burnt magnesia (electrically dead-burnt) might be successfully replaced by ordinary calcined magnesite, such as is used for magnesite cement in flooring. This product carries about 93 per cent magnesium oxide, with a small percentage of carbon dioxide, calcium oxide and silica.

The following formulas were used[5] in the making of several small briquets which were carefully dried and burnt at a temperature of approximately 1427 deg. C. in a small muffle furnace:

FORMULA 3A

45 grams zirconia (ground to pass through 80 mesh screen).
45 grams magnesium oxide (calcined).
10 grams water-ground zirconia.

The briquets after burning were of a brownish yellow cast, with a rather loose texture, but quite resistant to abrasion and of a fair tensile strength. The fire shrinkage at the above temperature was approximately 8 per cent linear measurement. One of the briquets at a white heat was dropped in a beaker of water, but no cracks were developed and the material was apparently as solid as before quenching.

FORMULA 3B

72 grams zirconia (ground to pass through 80 mesh screen.)
18 grams magnesium oxide (calcined).
10 grams water-ground zirconia.

Briquets made from this formula had very much the appearance of those produced by formula 3A. The fire shrinkage was approximately the same. The specific gravity was, of course, higher, owing to the greater percentage of zirconia present. The results of these tests were considered rather encouraging, and further investigations are now under way. The strong objection to the use of the magnesium oxide, particularly the calcined product, is the fact that it has an extremely high shrinkage. This of course is not true of the costly electrically shrunk magnesium oxide, but the tendency would naturally be toward the use of the cheaper calcined oxide.

Fire Clay Bond

As will be noted under fire shrinkage, briquet No. 4, mixed with a 10 per cent bond of refractory clay, showed extremely high shrinkage. It was decided, however, to manufacture a few standard-size fire bricks, using a 5 per cent bond of Warrior Ridge clay, as mentioned above. The zirconia was ground to pass through an 80-mesh screen, and thoroughly mixed in a dry pan with 5 per cent of the aforementioned clay. The mass was slightly moistened and formed into bricks in the same manner as is pursued in the manufacture of silica or chrome bricks. After thoroughly drying, these bricks were burnt in a silica brick kiln, at an estimated temperature of at least 1649 deg. C.

No figures were secured as to the fire shrinkage, but even this small percentage of clay caused the bricks to soften at a temperature well below the fusion point of the natural zirconia. The standard bricks made from the material weighed on an average 11¼ lbs. each.

To determine the behavior of the material when in contact with carbon at high temperatures,[6] a brick was made a part of one side of the trough of a granular carbon resistance furnace, the rest of the trough being made of magnesite brick, all being backed up by fire brick. A pyrometer tube was put in so as to give the temperature of the surface of the brick, next the carbon resistor, and temperatures read with a Wanner pyrometer. In about one half hour after starting, the temperature was 1800 deg. C. ± 25 deg., and it was held between 1750 deg. and 1850 deg. C., averaging 1800 deg. C. ± 25 deg. for 1½ hours. The furnace was then torn apart. The zirconia brick was just nicely red on the back (2½ in. from the resistor), while the magnesite bricks were much redder. From this and from the temperature of the fire brick backing when felt from time to time, it is plain that zirconia has a considerably lower thermal conductivity than magnesite, and quite probably the lowest of any available material that will stand 1800 deg. C.

The brick when put in place, had a slight crack, and this increased a little on heating, but not very badly. Magnesite bricks on both sides of it were badly cracked. A slight shrinkage was noted on the hot face, and the surface of the zirconia brick was slightly pitted and spongy. The spongy layer was only about ⅛ in. thick. The magnesite bricks were considerably more acted upon by the carbon than the zirconia bricks, their surfaces being eaten away uniformly over ⅛ in. Hence, as regards the action of carbon on the hot brick, the zirconia brick appears superior to magnesite, but inferior to carborundum.

The zirconia brick was not supporting any weight, and only the inner face reached 1800 deg. C. The brick had not really fused nor flowed of its own weight, *i. e.*, it might not have failed under a "cone test" at 1800 deg. C. Yet when the brick was picked up with tongs, they sank into the hot face, under gentle pressure, to a depth of ½ in.

The face of the brick was very plastic, and though it had not really fused nor flowed out of shape, the fact that the brick as a whole kept its shape was due to the stiffening effect of the comparatively cold back of the brick. If the whole brick had reached 1800 deg. C. and had been under any pressure, as in a wall with other courses of bricks resting on it, it would certainly have been pressed out of shape.

It therefore appears that 1800 deg. C. is the upper limit at which this brick (zirconia bonded with Warrior Ridge clay) could be safely used. It is, of course, quite possible that a brick bonded with water-ground zirconia and free from clay bond, might be stiffer and stand up at a higher temperature.

Therefore, while this particular brick is not as refractory under furnace conditions as the reported melting point of zirconia would lead one to expect, it is still refractory enough to be classed among the half dozen highest refractories; while not entirely free from shrinking and cracking, its behavior in this respect is far better than magnesite, although not as good as carborundum. Its heat conductivity is apparently less than any other of our high refractories. Its behavior in contact with carbon, while not perfect, is not so bad but that it can probably be controlled.

Zirconia Crucibles and Similar Shapes

In the manufacture of crucibles, muffles, etc., from zirconia, it should always be borne in mind that the material has an extremely low thermal conductivity. Hence, the walls of the crucible or other shape must be considerably thinner than would be the case if clay were used. Owing to the high tensile strength of zirconia

[5] By J. R. Adams under author's supervision.

[6] The following data was contributed by an experienced investigator, who requests that his name be withheld.

when properly bonded and burnt at a sufficiently high temperature, it is possible to make such objects without the danger of breakage through handling. Another important consideration in the use of zirconia in crucibles is its resistance to fluxes and slags. It has been suggested that water-ground zirconia might prove very efficient as a lining for graphite crucibles. Shallow dishes, trays and small crucibles have been made experimentally by hydraulically pressing various mixtures of coarse zirconia bonded with water-ground material, producing ware of high tensile strength and of extreme thinness. Shallow dishes have been pressed in this way, having a diameter of 6 in. and maximum thickness of not over ⅜ in.

Although this article does not concern itself with the uses and applications of chemically pure oxide of zirconium, it is interesting to note that two patents have recently been granted for the manufacture of utensils and the like from the oxides of the rare earths, such as thorium, zirconium, etc.

While the foregoing results should not be accepted as final or conclusive, they apparently presage important industrial uses for this new refractory.

Laboratory, Foote Mineral Co.,
Philadelphia, Pa.

The Dedication of the New Building of the Mellon Institute

BY W. A. HAMOR*

The new $350,000 building which will form the permanent home of the Mellon Institute of Industrial Research and School of Specific Industries of the University of Pittsburgh, was formally dedicated on Feb. 26. This building, the gift of Messrs. Andrew William and Richard Beatty Mellon, of Pittsburgh, was especially designed for the needs of the institute; it is distinctly

THE NEW BUILDING OF THE MELLON INSTITUTE IN PITTSBURGH

modern in every respect and complete facilities are provided for the investigation of manufacturing problems and for conducting industrial research according to the practical system of co-operation between science and industry, founded by the late director of the institute, Robert Kennedy Duncan. By this system an industrialist having a problem requiring solution may become the donor of a fellowship by providing the salary of the researcher selected to carry out the investigation desired, the institute supplying every facility for the work—laboratory space, the necessary apparatus and supplies, library facilities and advice of a staff expert in industrial research, etc.

The new home of the Mellon Institute is a five-story and attic building. The basement contains seven rooms: the main storeroom, the boiler room, the electric-furnace room, a heavy-apparatus room, a room equipped for low-temperature work, the machine shop and the kitchen. On the first, the main floor, are located the general office, the director's suite, the office of the editorial department, the library, the office and laboratory of the assistant directors, the assembly hall, a special apparatus room and a dark-room laboratory. The second and third floors each contain ten large research laboratories and nine small ones; the fourth floor, which is not finished, will contain an identical number of laboratories as soon as the growth of the institute warrants its completion. At the present time twenty-three fellowships are in operation and forty research chemists are engaged in a study of the variety of industrial problems under investigation at the institute.

While the Mellon Institute possesses an endowment of its own and has its own board of trustees, it is an integral part of the University of Pittsburgh. The dedicatory ceremonies were accordingly held in conjunction with the annual Charter Day exercises of the University.

The chancellor of the university, Dr. Samuel Black McCormick, presided at the dedication ceremonies, which took place at 11 a. m. in Soldiers' Memorial Hall, in conjunction with the annual Charter Day exercises of the University. Following the address of the day by Dr. Rossiter Worthington Raymond on "Knowledge and Research," Dr. W. J. Holland, director of Carnegie Museum and formerly chancellor of the university, made the presentation speech in connection with the dedication of the Mellon Institute, on behalf of Andrew W. and Richard B. Mellon, the donors. After a tribute to the generosity of the Messrs. Mellon, Dr. Holland said in part:

"In a certain sense this building is a memorial to Robert Kennedy Duncan. On one side of the entrance is a bronze slab inscribed with the name of Thomas Mellon; on the other side of the entrance is a bronze slab inscribed with the name of Robert Kennedy Duncan. But this splendid edifice erected upon the campus of our University is more than a cenotaph. It not merely commemorates the names and careers of those of whom I have spoken, but it is intended to serve as the seat of advanced inquiries along scientific lines, which will tend to the promotion not merely of intellectual culture, but of industrial success, and that not merely in this great 'workshop of the world,' where it is located, but throughout the land. In creating this institution our dear friends have been actuated by a high and intelligent purpose. Large experience in great industrial enterprise has taught them the importance of chemistry and physics in their application to the industrial arts, and they feel, that, wonderful as has been the progress made within the last century, there are untold mysteries in nature, which have not yet been revealed, but which, if uncovered, are capable of being used for the welfare of mankind. And so they have created and are today placing in the custody of you, gentlemen of the Board of Trustees, this institution, which is capable of becoming, when wisely and intelligently administered, a mighty implement for the advancement of human welfare."

Dr. George Hubbard Clapp, president of the board of trustees of the University, delivered the speech of acceptance. He expressed appreciation of the gift and understanding of the importance of the work for which the building has been erected.

The final ceremony of the exercises was the conferring of fifteen honorary degrees. The degree of Doctor of Laws was conferred on Edward Williams Morley, John Ulric Nef, Arthur Amos Noyes, Rossiter Worthington Raymond, Ira Remsen and Theodore William Richards.

The degree of Doctor of Science was conferred on John Jacob Abel, George Hubbard Clapp, Elbert Henry Gary, John Hays Hammond and Henry Marion Howe.

The degree of Doctor of Chemical Engineering was conferred on William Hultz Walker, Milton C. Whitaker

*Published by permission of Dr. Raymond F. Bacon, Director of the Mellon Institute.

and the degree of Doctor of Chemistry on Charles Lathrop Parsons and Edgar Fahs Smith.

Immediately after the close of the dedicatory exercises, the trustees, faculty and guests of the University met at a luncheon in the University Club. The remainder of the afternoon was devoted to an inspection of the new building of the Mellon Institute.

The recipients of honorary degrees were the guests of the University at the annual alumni banquet held at the Schenley Hotel from 6 to 8:30 p. m. The speakers at this dinner were Dr. Raymond F. Bacon, director of the Mellon Institute, who responded to "The Mellon Institute"; Dr. Walthor Biddle, who gave an historical sketch of the department of chemistry of the University; Hon. Elbert H. Gary, chairman of the United States Steel Corporation; Dr. Theodore William Richards, who spoke on "The Practical Use of Research in Pure Science" and extended Harvard's congratulations to Pittsburgh upon the acquisition of the Mellon Institute; and Chancellor Samuel Black McCormick, who completed the toast list with an eloquent response to "The University," in which he stated that the gift of the Mellon Institute had placed a great responsibility upon the University of Pittsburgh as well as having been a priceless acquisition; that the University was ready to meet the responsibility and, he felt sure, would show the donors and the country at large that it would make the most of the great benefaction.

After the banquet the new building of the Mellon Institute was thrown open for a reception of friends of the institute. The rooms of the main floor were used for the reception, although the entire building was open for inspection. On the evening of Feb. 27, the first Mellon lecture was delivered by Prof. John Jacob Abel, of Johns Hopkins University, in the assembly hall of the institute; Dr. Abel's subject was "Experimental and Chemical Studies of the Blood and Their Bearing on Medicine."

Personal

Mr. **T. A. Bennett,** who for the past five years has had charge of the conveyor and elevator belt sales of the B. F. Goodrich Company, Akron, Ohio, is severing his connection with the Goodrich Company on March 1st, to become the assistant to the general sales manager of the New Jersey Zinc Company, with offices in New York City. Mr. Bennett will be succeeded by Mr. **J. D. Mooney,** formerly special mining representative for the Goodrich Company.

Mr. **O. M. Bilharz** has resigned his position as technical manager for the St. Joe and Doe Run lead companies in southeastern Missouri.

Dr. John C. Branner, president of the Leland Stanford, Jr., University, Cal., has resigned to take effect July 31, 1915.

C. F. Burgess Laboratories is the new name of the Northern Chemical Engineering Laboratories of Madison, Wis. There is no change in management or ownership, and the concern of which C. F. Burgess, formerly professor of the University of Wisconsin, is president, will continue as heretofore its practice in chemical engineering, research, and industrial development.

Mr. **Arthur Crowfoot** has been appointed superintendent of the concentrator of the Arizona Copper Co., Morenci, Ariz. He was formerly engaged in various capacities at the Boston & Montana reduction works of the Anaconda Copper Mining Co.

Dr. Carl Hering, of Philadelphia, Pa., has been elected a Fellow of the Association for the Advancement of Science.

Mr. **V. D. Howbert** was recently elected president of the Colorado School of Mines Scientific Society, a student organization. C. E. Carstens is vice-president and F. E. Briber secretary.

Dr. W. C. Huntington has been appointed commercial agent in charge of the Chicago branch of the Bureau of Foreign and Domestic Commerce. He succeeds **Mr. H. H. Garver,** who has accepted the position of foreign trade commissioner of the Chicago Association of America.

Mr. **W. J. Kee, Jr.,** for the past four years superintendent of the Argentine acid plant of the National Zinc Company (formerly the United Zinc & Chemical Company), has resigned to become connected with the new acid plant designed by Mr. Utley Wedge for the Anaconda Copper Company, Anaconda, Mont.

Mr. **Edward W. Lawler,** for many years with the Hardinge Conical Mill Co., the Abbe Engineering Co., and other concerns, is now connected as sales engineer with the Jeffries Mfg. Co., with headquarters at 77 Warren Street, New York City.

Mr. **John L. Malm** has returned to Denver from a professional trip to Chicago.

Ricketts & Banks, New York, have dissolved their copartnership by mutual consent, and each will continue separately in business as mining, metallurgical and chemical engineers. **Ricketts & Co.** will be located at 80 Maiden Lane, and **Dr. John H. Banks** at 61 Broadway.

Mr. **L. T. Ticka** has resigned his position as mechanical superintendent of the International Smelting Company, Tooele, Utah, to become the mechanical superintendent and engineer for the St. Joseph Lead Company, Bonne Terre, Mo.

Mr. **H. E. Tuttle** has severed his connection with the Edgar Zinc Company and is with the Fink Furnace Company, Chicago.

Obituary

Frank L. Clerc died in Denver, Colo., March 9, 1915. Mr. Clerc had long been identified with the zinc industry and was well and favorably known as a metallurgist in that branch of ore treatment. Although he had not been engaged in active practice in recent years, his interest in his chosen line of work did not abate, and he continued his studies and researches practically up to the time of his death. As a contributor to technical literature he was known to a wide circle of metallurgists. Shortly before he returned to Denver from an eastern trip during the winter, he was engaged in gathering together his contributions which had appeared in this journal and elsewhere, with the idea of republishing them in book form. In recent years he had been much interested in the metallurgical problems confronting the producers of low-grade carbonate and silicate zinc ores at Leadville. On this subject he proposed a number of methods of procedure, bearing particularly on igneous concentration. He also invented a form of furnace that he considered specially applicable to the reduction of the zinc oxide that would result from fire concentration of low-grade ores.

Mr. Clerc was born in Pennsylvania on February 22, 1851. He studied and graduated at Lehigh University and came west, finding a field for his activities in the zinc district of Missouri and later in New Jersey. At different times he was identified with the faculties of the Massachusetts Institute of Technology and the Colorado School of Mines. He is survived by two sisters, one of whom lives in Phillipsburg, Pa., and the other in Wilton, Conn.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Aqueous Bath, Electroplating Alloys

273,324, March 6, 1883, Joseph M. Thomas, of Auburn, N. Y., assignor to Byron C. Smith, of same place.

Relates to electrodepositing brass upon steel, malleable, cast or wrought iron, or upon tin, lead, bismuth, type or britannia metal, from a solution prepared as follows: 1 ounce (avoirdupois) of crystallized acetate of copper is dissolved in 8 ounces (liquid measure) of ammonia water of 26 deg. B.; in 1 gal. of distilled or rain water, at 165 deg. Fahr., is now dissolved 18 ounces (avoirdupois) potassium cyanide; to this cyanide solution is now added 2 ounces crystallized acetate of zinc, with stirring until dissolved; the acetate of copper and ammonia solution is now added and lastly ¼ ounce (liquid measure) commercial hydrocyanic acid. The solution thus prepared is heated to about 165 deg. Fahr. and used as the electrolyte with either copper and zinc or brass as anode. The color of the brass deposit is determined by the current strength; a strong smooth current is recommended.

477,350, June 21, 1892, Edward T. Burrowes, of Portland, Maine.

Relates to electroplating wire-screen-cloth made of brass, copper or composition or other bright smoothly finished wire, so as to diminish its excessive brightness, toning it down to a darker and more subdued color, rendering it less conspicuous and better adapted for house-screen use. The electrolyte is made by dissolving 30 lb. of copper sulphate, 1½ ounce caustic potash, 10 lb. zinc sulphate, 6 ounces tin chloride, 5 lb. salammoniac and 8 ounces muriate of iron. This is deposited electrically by means of an anode composed of 8 lb. of copper and 1½ lb. each of tin and zinc. The plating process changes the bright-wire screening to a fine dark-brown color resembling statuary bronze, which is said to be permanent and not liable to be affected by the atmosphere.

487,176, Nov. 29, 1892, Sherard Osborn Cowper-Coles, of London, England, assignor of one-half to the London Metallurgical Company, Ltd., of same place.

Relates to electrodepositing upon metals or other suitable objects an alloy better adapted than silver to resist the tarnishing influences of the atmosphere. The alloy consists of zinc and silver, or cadmium and silver, or zinc, cadmium and silver; the proportions varying from 35 per cent to 25 per cent, or less, of the zinc or cadmium; or a cheaper alloy may be made with from 40 per cent to 90 per cent of the base metal. The electrolyte is prepared as follows: A suitable quantity of cyanide of zinc or cadmium is dissolved in a solution of cyanide of potassium, so as to form a double salt having an excess of cyanide of potassium. To this solution is added a small quantity of the double salt of the cyanides of potassium and silver. The electrolyte thus prepared may be used hot or cold. An anode of approximately the composition of the alloy deposit desired is employed, the hardness of the alloy varying with its composition. (See also his later patent, No. 512,160.)

512,160, Jan. 2, 1894, Sherard Osborn Cowper-Coles, of London, England, assignor to the London Metallurgical Company, Ltd., of same place.

Relates to the alloy deposit produced by the process described in his patent, No. 487,176, which should also be consulted. The alloy consists of silver and cadmium, silver and zinc, or silver, cadmium and zinc or any other known metal or metals, other than indium, having a specific gravity between 6.5 and 9, and boiling at a temperature between 710 deg. C. and 1045 deg. C., these alloys being employed with or without the addition of any or all of nickel, cobalt, tin and chromium. The anodes employed in the electrodeposition may be carbon, lead or platinum or of an alloy similar to that to be deposited. The electrolyte may be composed of compounds of silver dissolved in water or in alkaline cyanides, or alkalies or other bases, and may be mixed with solutions of compounds of zinc or cadmium, or of other metals of the alloy to be deposited; the electrolyte may also contain salts of the alkali and alkaline earth metals.

543,824, July 30, 1895, Henry J. Altman, of New York, N. Y., assignor of one-half to Max H. Fischer, of same place.

Relates to electrodepositing an alloy coating consisting of platinum with another metal or metals having a specific gravity of between 2.6 and 9, except manganese, antimony and chromium, which are not suited to his purposes. The preferred alloy consists of platinum and nickel, with about 1 per cent platinum; or may consist of a larger proportion, as one part platinum and three parts of nickel. The alloy deposit forms a brilliant coating resembling silver, but less liable to tarnish or corrode. The electrolyte contains the metals to be deposited as salts and is made by dissolving separately 12 ounces of nickel and ammonium sulphate in 7 pints of water, ¼ ounce of tetrachloride of platinum in ½ pint of water, 1/6 ounce of caustic soda in ½ pint of water; the caustic soda solution is added to the platinum solution and to the mixture is added 1¼ ounces of ethylamine or its equivalent. To this mixture is then added the nickel solution and then 1½ ounces of sodium chloride dissolved in water is added. The anode used preferably has the composition of the coating desired or may be of platinum or carbon, etc. For alloys of different composition, the proportions of the salts should be varied accordingly. In place of ethylamine there may be used any other organic base containing nitrogen, as methylamine, pyridin, etc.

563,723, July 14, 1896, Hans Alexander, of Berlin, Germany, assignor to Louis Potthoff, of Long Island City, N. Y.

This patent was reissued, No. 11,624, dated Aug. 3, 1897. It relates to plating iron or steel with a coating of zinc, as a substitute for the galvanizing of iron by molten zinc. An electrolyte containing a basic aluminium salt is made as follows: To a solution containing in 100 parts of water from 5 per cent to 8 per cent of chloride of aluminium is added sufficient metallic zinc (or tin or tin and zinc) as it will dissolve. While dissolving the solution should be kept boiling, the water evaporating being replaced. Instead of dissolving the metal chemically it may be dissolved as an anode. To the resulting solution is added from 0.2 per cent to 0.3 per cent of chloride of zinc (or of chloride of tin or of the chlorides of zinc and tin) and the boiling continued for about one-half hour. The solution may also contain an organic acid, as citric or tartaric acids. A small quantity of chloride, or sulphate, or nitrate of mercury may also be added. The deposit obtained from such a solution is said to be compact, smooth and durable.

Book Review

Laboratory Manual of Glass Blowing. By **Francis C. Frary, Ph.D.** Small 12mo., 57 pages, 75 cents. New York and London: McGraw-Hill Book Company, Inc.

A brief manual of instructions in the art of glass blowing that will be of value not only to beginners but also to those with some skill. The instructions are clear and concise and are well supplemented by illustrations.

The Contributions of Chemistry to the Industries of the United States

The most prominent feature of the celebration of the fiftieth convention of the American Chemical Society, held in New Orleans last month, was the elaborate symposium of papers on contributions of the chemist to the American industries before the Industrial Section. Introduced by a brilliant address by Dr. Arthur D. Little on the industrial resources and opportunities of the South and concluded by an able summary by Dr. Bernhard C. Hesse of the record of achievements of American chemistry, the symposium proper comprised nineteen papers on the decisive influence which chemistry and the chemist have had on the development of the wine industry, the copper industry, the corn products industry, the asphalt industry, the cement industry, the sugar industry, the incandescent gas mantle industry, the textile industry, the fertilizer industry, the soda industry, the leather industry, the flour industry, the brewing industry, the preserved-foods industry, the potable water industry, the celluloid and nitrocellulose industry, the glass industry, and the pulp and paper industry.

This record of chemical achievements is certainly impressive. It is the more impressive as in a way these nineteen papers scratched only the surface. For instance, of all the contributions of chemistry to metallurgy, only those relating to copper metallurgy were dealt with. Yet it is perfectly true to say that the functions of the chemist are now looming large besides those of the mechanical and mining engineer in the modern metallurgy of any and every metal, not the least in the biggest of all metallurgical industries, that of iron and steel. And the electrometallurgical achievements of the last decades would have been simply impossible without the chemist; the aluminium industry would simply not exist had it not been for the work of the chemist.

In spite of its shortcomings this symposium was very successful. It was timely. With the popular outcry in our ears that lack of "spunk" has prevented American chemists from creating a complete dyestuff industry, it was necessary to impress on the public the fundamental fact that the sphere of influence of the chemist reaches far beyond the boundaries of the chemical industries. Indeed, the influence of chemistry reaches into every industry, just as does the influence of the mechanical engineer. But while the mechanical engineer is usually called in at the beginning of an industrial development, the function of the chemist starts generally much later, when refinements, recovery of by-products and the avoidance of waste become important. His work is not less important than that of

the mechanical engineer, but it is not equally visible, it does not impress itself directly on the public.

Of course, as all industries depend upon materials and very often upon materials which are not provided by nature but must be specially made and fitted to the case, and as this is the more true the further an industry advances, all industries depend upon chemistry. This is perfectly obvious, but it does not state the whole case. Chemistry is more than a mere collection of facts on elements, compounds, and materials. It is a habit of thought, a viewpoint. When the Perkin medal was recently presented to Dr. Edward Weston, Dr. Baekeland in his address (published in our March issue) showed in a very clever way how the "chemical viewpoint" which Weston had acquired in his youth by his electrochemical work, had helped him later in his electrical engineering work. What is true of an individual evolution is more broadly true of broad industrial developments. The solution of an industrial problem depends, first of all, upon the correct formulation of the problem. And the correct formulation of the problem depends on the viewpoint—a narrow viewpoint, based on man-made classifications and conceptions is fatal. Every new and true viewpoint that can be brought to bear upon a problem is of inestimable value. For this reason alone the chemist cannot be ignored by any industry whatsoever. What he has done in the past for the development of the American industries entitles him to hold up his head with pride. This was the keynote of the New Orleans symposium.

Nor does the American chemist need to be ashamed of the development of the American chemical industries proper. While this country has no complete dyestuff industry, it has an electrochemical industry that is the child of the American soil and is not equalled anywhere in the world. As Mr. Lidbury put it in his brilliant presidential address before the American Electrochemical Society last week, "in spite of its youth, the absence of the electrochemical industry from among the industries of the country would cause such industrial disturbance that the plaint of the wearer of many colors, always imminent but not up to the present moment audible, would pass unnoticed."

Conditions in Mexico

Villa's recent proclamation of new laws governing mining in Mexico has complicated an already intolerable situation and has stirred the representatives of foreign mining companies in Chihuahua to earnest protest. Although life and liberty there have long been in jeopardy and "57 varieties" of paper money have created financial chaos, no concerted protest has been made against high-handed methods of government until the present decree threatened the confiscation of mining property. The protest has already borne fruit; our State Department announces that exemption from the terms of the decree can be secured on proper representations to the Minister of Fomento at Chihuahua.

The reformed Article 51 of the mining law provides, in brief, forfeiture of mining property for (1) nonpayment of taxes; (2) voluntary suspension of work; (3) abandonment of work; (4) insufficient exploitation, and (5) failure to "maintain in activity at least one working exploitation within each five pertenencias (10 acres), or fraction thereof." The decree announces that these restrictions are necessary in order to insure mining activity so "that the exchequer should lose none of its incomes which are indispensable for the fulfillment of its obligations." The latter evidently rest heavily on the government!

Mexican ideas of justice are beyond comprehension. Having created conditions that forced prudent people to leave the country and abandon their property until such time as they could return to it in safety, the Mexican authorities now decree that such property shall be forfeited to the country unless it is made productive and that at once. Payment of taxes, often in duplicate to successive and opposing chieftains, is not sufficient to hold title in the absence of actual operation. The fact that supplies are scarce or even unprocurable; that operations could not be conducted except at a loss, and that the terms of the decree are ridiculous from an engineering standpoint—none of these things move the Mexican chief.

Villa has been a popular leader, as leaders go in Mexico. His cause has had moral support from such engineers as have been disposed to take a partisan stand in the interests of peace in Mexico. Hitherto he has been considerate and tolerant, and has won a substantial following. Recent press dispatches indicate military reverses to his arms, but such disasters will not be as potent in effecting his downfall as will the blind and foolish enforcement of his mining decree.

The Distribution of Steel

A superstition has lately arisen that a very large proportion of the steel now being produced in the United States is passing into "war material," and it may be well not only to suggest that such is not the case, but since we have brought the subject up, to point out that the distribution of steel, into various consuming industries, is very different indeed from the distribution that obtained only a few years ago.

We must define our measuring rod first. It is commonly reported that the steel industry has lately been operating at about 70 per cent of its capacity. It is probably not far wrong to assume that the actual production in 1913, the record year, represented about 85 per cent of the present productive capacity. If so, production is now at the rate of about 25,000,000 gross tons annually of steel ingots and 19,000,000 gross tons of rolled steel, weighed in the form in which the steel leaves the hot rolls and shears.

Since the early weeks of the war there have been constant rumors of very large orders being placed for steel for war purposes, but the official statistics of exports as they have appeared month by month have successively proved the incorrectness of the major portion of the reports that had been circulated. In recent weeks the reports have become more insistent, but in the light of previous experiences we are justified in discounting them very heavily. The latest official returns, made public

within the past ten days, are for February and show total exports of all iron and steel returned by weight of 144,366 gross tons, this comparing with 139,791 tons in January. While this shows an increase, the best month since the war started lies as far back as October, with 147,293 tons, so that the February statistics disclose no definitely increasing tendency in the total iron and steel exports. Making allowance for the scrap, pig iron and cast iron included in the February total there was left material representing about 125,000 tons of rolled steel, representing 7.9 per cent of the current production. If the exports had since increased by one-half, which is quite improbable, they would represent only 12 per cent of the current production. In any event, a very considerable part of the material exported is not for war purposes. Nor can any very large tonnage of war steel be concealed in other listings than as tonnage exports, as unclassified manufactures of steel show decreases instead of increases since the war started. Even with a large percentage increase in the exports of lathes and other machine tools, lately required for the manufacture of arms and projectiles, the exports of this class of machinery have increased only by something like $1,000,000 per month in value, so that the weight of iron and steel involved can amount to but a very few thousands of tons a month. Exports of motor trucks appear large simply because there was very little such business before the war, an average of less than 100 trucks per month, while the exports in February were 1002 trucks and, in the eight months ending February, 4974 trucks. There was, however, a large decrease in exports of pleasure cars. The exports at present evidently represent less than 5000 tons of iron and steel per month, and not much more than before the war.

There is reason to conclude, therefore, that the total exports of the United States do not involve more than 15 per cent, possibly no more than 10 per cent, of the steel now being produced.

The steel that remains at home is being distributed quite differently than a few years ago. In 1906 the production of steel rails for home consumption was 3,650,000 tons, or 21 per cent of the total finished steel output. At the present time rails for domestic consumption represent considerably less than 10 per cent of the current steel output. In 1906 structural shapes represented more than 12 per cent of the total steel output. The reports of fabricated steel contracts let show an average of 51,000 net tons per month in December, January and February, and 110,000 net tons in March. A considerable proportion of this tonnage is plates, while there is very little consumption of structural shapes in car building and miscellaneous work, and it may be estimated that about one-half as large a percentage of the current steel output is passing into structural shapes than was the case in 1906. In 1906 nearly 7000 locomotives and 240,000 freight cars were built, involving about 4,000,000 gross tons of steel, or 23 per cent of the steel output. To-day it is certain that less than 5 per cent of the current steel output is passing into cars and locomotives for domestic use.

In practically all the other lines of steel consumption the percentages have greatly increased since 1906. The motor-car industry has risen from practically nothing, and in the past few months, the height of the manufacturing season, has probably been taking from 3 to 5 per cent of the current steel output, apart from its consumption of castings and forgings. The tin-plate industry is consuming more than 6 per cent of the finished steel output at present, against 3.3 per cent in 1906. The sheet industry accounted for 6.2 per cent of the steel output in 1906, and now involves a slightly larger proportion. In wire, wrought pipe and merchant bars the proportions have very greatly increased.

It is possible to generalize from this comparison and to observe that steel is passing much more into the articles of common everyday consumption and much less, proportionately, into large structures, such as bridges, buildings, etc., and railroad use. By no means does it follow, of course, that the altered distribution is to be permanent. Rather it may be suggested that since it has been extremely difficult in the past nine months or more to effect any new financing, the time may come when large undertakings will be resumed in numbers, with, of course, no decrease but rather an increase in the common everyday consumption of steel. If so, there will be a total demand for steel that the industry as now constituted cannot possibly supply. It is reported to be operating at 70 per cent of capacity at present and it is asserted that sufficient labor could not be found to operate it at 100 per cent. The situation is fraught with interesting possibilities for the next few months.

The Government's Alaskan Railroad

Based on the acquisition of the existing Alaska Northern Railroad as a first link, the Government has undertaken the construction of a railroad from Seward to Fairbanks, Alaska, a distance of 471 miles. A branch line of 38 miles is to be built into the Matanuska coal fields. The price to be paid for the Alaska Northern is $1,150,000, a rate per mile much less than half the estimated cost for constructing the balance of the road. The commission's estimate for building 438 miles of railroad is $26,800,000.

The official route, announced by President Wilson on April 10, is from Seward, on Resurrection Bay, along the Kenai Peninsula to Turnagain Arm of Cook Inlet, thence through the Susitna Valley, across Broad Pass and down the Nenana River to Fairbanks on the Tanana River. The work is to be under the direction of the Alaska Engineering Commission, consisting of William C. Edes, chairman; Lieutenant Frederic Mears and Thomas Riggs, Jr. It is expected that about 40 miles of railroad can be constructed this year.

The adopted route will open and exploit a territory not now served by a railroad, and will assist materially in the development of two important coal fields: the Matanuska and the Nenana. A supply of fuel from these districts will be of the greatest importance to the industrial development of Alaska. Fairbanks, the inland terminus of the road, is the center of an important gold mining industry.

Readers' Views and Comments

Government Publicity Methods

To the Editor of Metallurgical & Chemical Engineering.

Sir:—Criticism of Dr. Rittman continues to fill a considerable portion of the oil journals and shows little signs of abating after more than six weeks from the date on which his discoveries were announced to the public. Since much of this criticism is based on an incomplete knowledge of the real facts in the case and is decidedly unjust to Dr. Rittman, I feel that it is only proper that I should make known certain conditions which up to now have apparently not been given proper consideration.

Dr. Rittman and myself are rivals in the development of oil-converting processes, but I do not want any advantage in this contest to come to me because of wholly unmerited personal attacks on Rittman, or criticism of him which is not only unfair, but almost wholly misdirected. In the May and June (1914) numbers of the "Journal of Industrial and Engineering Chemistry" there will be found a most scholarly and comprehensive article by M. C. Whitaker and W. F. Rittman, in which the basis of Dr. Rittman's work in oil cracking is discussed in a thoroughly scientific spirit. This article should be sufficient to establish the scientific standing of Dr. Rittman, and forces anyone who gives it careful attention to admire the patient work, and the brilliant results which were obtained. That Whitaker and Rittman have done most important and valuable work in the cracking of oils will not be doubted by anyone who takes the time to read the results obtained in these important papers.

That there have been some very unfortunate and probably highly improper publicity methods used in bringing the Rittman work before the public is undoubted, and my purpose in this statement is to place the blame where it belongs. Up to now it has been laid on both Rittman and on the newspapers, but I believe I can show that in neither case is the criticism justified.

Although Congress has repeatedly insisted that no part of the funds allotted to the government departments are to be used in press agent work, it is a matter of common knowledge that several of the government departments systematically violate these provisions. The Bureau of Mines, in particular, maintains a very active publicity department, the work of which can be well seen in the recent Rittman announcements, including the numerous personal interest stories of Rittman's muscular development, his football prowess, his helpful wife, etc., etc., ad nauseam. No person who knows anything of the scientific work of Rittman can believe for a moment that he has been a willing party to publicity efforts of such a nature.

About a year ago the newspapers of this country were filled with radium press notices. A bill was before Congress carrying an appropriation of $450,000 for radium research by the Bureau of Mines, and apparently the bureau press agents worked overtime in their efforts to convince the people of this country that radium had almost miracle-working properties. Day after day the newspapers carried press notices of a misleading, if not of a wholly false character, and no efforts seem to have been spared in this compaign of publicity. In the Associated Sunday Magazines, which form the supplement of many Sunday newspapers, on Feb. 22, 1914, there was published an article by Franklin K. Lane, and using his official title as Secretary of the Interior. The opening sentence of this article is as follows:

> "When we reflect that the production of every additional half-gram of radium means the saving of a human life a day from the ravages of cancer, no question can remain of our obligation to conserve and make available for use all the radium resources of this country."

At the time this article was written it is not at all certain that a single human life had been saved by radium. As a matter of fact, eminent medical authorities insisted at that time, and still insist, that no case of deep-seated cancer has ever been cured by radium, and that its exploitation as a curative agent for cancer has been due largely, if not wholly, to the efforts of parties who expected to financially profit by it.

Personally I believe that the numerous misstatements which went through all the American newspapers a year ago were part of a systematic and organized campaign for the purpose of insuring the passage of the Bureau of Mines appropriation bill of $450,000 for radium research. There are strong reasons for believing that the officials of the Bureau of Mines knew at the time that radium had no such curative powers as were being claimed for it.

The many points of similarity between the radium publicity methods and the methods recently used to introduce the Rittman discoveries to the public, will probably be noted by anyone who cares to look into the matter. As a matter of fact I have personally seen some of the press notice sheets which were handed out to the newspapers of this country in regard to the Rittman publicity. The newspapers published these sheets in practically the identical form in which they came to them.

I do not feel that the present is a proper time to enter into any detailed explanation as to just what motives are behind the work of the Bureau of Mines in exploiting the present cracking process. I will only state my belief that beneath it all there will be found certain conditions which go back somewhat over five years and which are not in any way creditable to certain officials of the Bureau of Mines, who are concerned in the matter. I believe it will be later shown that many of the details of my experiments in bringing about equilibrium conditions in hydrocarbons, with the production of large yields of gasoline, have been known to certain officials of the Bureau of Mines for a number of years past, and that Dr. Rittman was only employed by the bureau after the publication of his brilliant work at Columbia University had proved him to be a man particularly able to serve the interests that certain officials of the Bureau of Mines had in view.

There are, however, some points in regard to this recent work of the Bureau of Mines which are probably deserving of more or less immediate attention. It is known that in the development of the Rittman process, as in the development of the radium plans of a year ago, the bureau is working in coöperation with certain private interests and under agreements which are kept carefully secret.

We know to-day that a private company, the Aetna Explosive Company, has agreed to expend $200,000 in the development of the benzol and toluol end of the Rittman process, and that at present development work on a very large scale is going on in Pittsburgh. We also know that until this work is completed no further information is to be given out in regard to the process.

It is most interesting to note that it is an explosives

concern which has advanced the money to develop this process. It is also significant that the Rittman process is stated to be capable of producing a very good yield of toluene, a material which is very much in demand at the present moment, because of the war abroad, nitrotoluene being the principal explosive used in shell charges. Since the war commenced my laboratory has been receiving repeated requests for toluene and nitrotoluene, and I personally know that inquiries for toluene and nitrotoluene in very large amounts have been made in this country in the last few months.

At this psychological moment, when any process for making toluene economically can be made to yield profits of several million dollars within the course of a comparatively few weeks, an explosives concern friendly to the Bureau of Mines makes an agreement with the bureau by which it spends $200,000 in developing the Rittman process for the production of toluene from petroleum. During the life of this secret agreement it is understood that the Aetna Company is to have the exclusive use of the Rittman inventions and of all the products which can be obtained by their operation.

It is quite evident that to carry out the successful development of any scheme for using a government process and government chemists at the present time in the production of toluol, it is most desirable that the government officials should have no knowledge as to the use to which the toluol is to be put, or its final destination. With the painstaking thoroughness which characterizes much of the work of the Bureau of Mines apparently even this detail has been carefully attended to, and it is with great relief that we read in a letter written by Van H. Manning, of the Bureau of Mines, to the *Oil, Paint and Drug Reporter* under date of March 22, 1915, as follows:

"The products derived are, of course, to be the property of the Aetna Company, and this Bureau is not aware what arrangements have been made by such company for the use or disposition of the products."

I think it is very fortunate indeed that Mr. Manning has thus been kept in entire ignorance of the purposes for which the Aetna Company desires the toluene. He is probably firmly of the belief that this toluene is to be used in making whitewash, or soap, or alarm clocks. Anything, in fact, except explosives. How very fortunate it is that in all the negotiations which have been carried out between the Aetna Company and the Bureau of Mines, neither Mr. Manning nor any of his associates should have evinced any interest as to the reasons which actuate the Aetna Company to expend this large amount of money in experimental work in return for the exclusive right to use the process during the time that the present high prices for toluol exist. Later, when all the war orders have been filled, and toluene sinks to its normal level, below the price at which toluene can be economically produced by the Rittman process in competition with coal tar distillates, then, no doubt, the Rittman process will be thrown open to the general use of the American people. But for anyone to believe that it will thus be thrown open to the use of the general public untill all the "cream" has been cautiously removed, or until the process is found to be economically inoperative, for anyone to believe that, either betrays entirely unjustified credulity, or a faith in human nature which is not in line with the past actions of the very clever politicians of the Bureau of Mines.

I do not want these statements of mine to be in any way construed as a wholesale condemnation of the working of the government departments. Some of the government departments follow as high a standard of ethics as exist anywhere. I believe the patent office, in particular, before which the Rittman process must have its final review, is wholly incorruptible. Neither do I believe that Dr. Rittman is in any way responsible for, or a knowing party to, anything improper in the plans of the Bureau of Mines. Men of the highest scientific standing and ability have apparently in the past been used as tools by the Bureau of Mines in affairs which these men would have been the first to denounce had they known their true inwardness.

I believe the time has come to turn the searchlight of publicity upon the government officials and the government departments who are concerned in such matters as I have here referred to.

Pittsburgh, Pa. WALTER O. SNELLING.

The Western Metallurgical Field

Concentration of Carnotite Ores

The concentration of low-grade carnotite ores, which has been talked about and experimented on for so long, is now an accomplished fact, being in operation in two plants in Southwestern Colorado. The Standard Chemical Co. and the National Radium Institute have perfected methods of concentration and each has a plant that is in continuous and successful operation, that of the latter under the technical direction of the Bureau of Mines.

The necessity of concentrating the low-grade carnotite ores of Colorado has long been recognized on account of the isolation of the region in which they are found, the economic necessity of treating them at some point distance from the place of their occurrence and the high cost of transportation. In the first careful investigation made on these ores and their treatment by Dr. Herman Fleck and Prof. W. G. Haldane of the Colorado School of Mines the desirability of concentration was recognized and the principles of a process were disclosed. In their report, which was embodied in that of the Commissioner of Mines for Colorado, 1905-6, they state:

"Perhaps no method of ore dressing could be succesfully applied. The extremely fine state of division of the mineral precludes this. Magnetic methods have been experimented with, but to no effect. A microscopic observation made on the ore showed, in a sample of ore from hydraulic, carrying about 4.5 per cent. uranium oxide, that the somewhat worn but yet distinct quartz crystals composing the grains were cemented by carbonate of lime, and that the carnotite adheres to the face of the crystals after rubbing the grains free from most of the carnotite dust. This suggested a method of preliminary sliming and subsequent attrition, whereby the values in the form of slimes might be easily filter pressed or settled. Machinery for the purpose of subjecting the sand grains to attrition could readily be devised."

Subsequently, other engineers experimented along this line, and the present processes in operation are based on these principles. In the Bureau of Mines *Bulletin* 70, Messrs. Moore and Kithil discuss both wet and dry methods of concentration, and give experimental results. The definite establishment of concentrating mills in the carnotite-producing region of Colorado is an event of economic importance in the uranium, vanadium and radium industries.

Alaska Gastineau Mill

When the first unit of the new mill of the Alaska Gold Mines Co. was put in operation on February 18, 1915, the promoters of a tremendous enterprise in gold mining and milling began to see the fruition of several years of labor. That the operation of the first unit started so favorably and demonstrated a capacity beyond the calculations of the designers, is a tribute to the

conservative care with which the work has been done. As first planned, the mill was to have a total capacity of 6000 tons in 24 hours, each of the four units having a capacity of 1500 tons. Mr. Jackling has stated that it now appears that the capacity will be 2500 tons per unit, or a total of 10,000 tons per day, and that the recovery is fully up to his expectations and will check with the experimental results. The other sections of the mill will be in operation at intervals of from 40 to 60 days, and in the meantime the mine will be sufficiently opened to provide the tonnage. The ore thus far treated, coming from six widely separated points in the mine, is reported to average nearly $2 per ton.

Interest in this mill centers in the radical departure from the customary methods of milling gold ores. In general, the method adopted follows the process which is in use in concentrating low-grade prophyry copper ores in Utah and Arizona. The ore passes over grizzlies, and the oversize is broken in jaw crushers. The grizzly undersize and the product of the jaw crushers is further crushed to 2-in. size in gyratories. This is followed by roll crushing in Garfield rolls of 72 in. and 54 in., with intermediate screening. Impact screens of 10-mesh finish the dry-crushing and screening process.

Concentration begins on Garfield roughing tables and is continued on Wilfley tables. The discard is classified, the coarse portion being ground in tube-mills and the concentrating process repeated. Concentrates of different grade are the products, and these are shipped to reduction works. Some high-class concentrate is reduced to base bullion at the mill.

Chloridizing at Park City, Utah

Resumption of operations at the Park City Mills is scheduled for May 1. This plant started operations last Fall, but a short run was unsatisfactory to the operators, and it was decided to make a change in the roasting furnace in which the chloridizing operation is performed. In view of the success of the Holt-Dern roaster at the mill of the Mines Operating Co., at Park City, it was decided to install a furnace of that type. This machine has been completed and is practically installed. The ore to be treated will come from the American Flag mine. Its principal value is in silver, with some gold, lead and copper, being a typical "complex" ore. The mixture for the roast contains ore, salt and coal, and the product is subjected to leaching with a salt solution. The metals are recovered by precipitation. Details of the process as carried out at the mill of the Mines Operating Co. have been given in this journal, July, 1914, page 431. An article on a similar process at Silver City, Utah, appeared in our issue for December, 1914, page 757.

Zinc Smelting at Pittsburg, Kansas

Information from Joplin is to the effect that the Pittsburg Zinc Co. has resumed operations at its smelter, which has been idle for several years. The plant has 1600 retorts, and coal is used for fuel. J. G. Starr is in charge of operations, and associated with him are members of the Lanyon family who have long been connected with the zinc industry.

Federal Investigation of Smelters

Too late for report in our last issue we learned that Federal authorities are investigating the possibility of an unlawful combination of smelters handling Missouri lead ores. It is alleged that a combination exists to fix prices and control the market for lead ores. The Department of Commerce made a perliminary probe and was followed later by the Department of Justice. The State Attorney General also has indicated his willingness to join in the search. No announcement has been made as to the results of the investigation.

Company Reports

Nevada-Douglas Consolidated Copper Co. has been reorganized, the new company including the former Nevada-Douglas Copper Co. and Moore Mining Co. The company is erecting a mill for the treatment of copper ore by the Rankin nitric acid leaching process. The plant is not complete, work being suspended about the time the European war broke out. An assessment has been levied to provide funds to complete the plant and put it in operation.

The American Smelting & Refining Company's sixteenth annual report, covering the calendar year 1914, shows total earnings of $10,811,915; depreciation, $1,540,350; loss incidental to European and Mexican wars, $240,000; net earnings applicable to dividends, $9,031,565; preferred stock dividends, $6,017,450; common stock dividends, $2,000,000; surplus, $1,014,115.

The conditions of affairs in Mexico has operated to decrease the company's earnings. In August it appeared as though operations might be resumed at the Mexican smelters, but such was not the case. Conditions there continue to be a source of worry to the directors.

The total volume of the year's business was $200,925,625, of which 4.49 per cent, or $9,031,565, was available for dividends. The value of the four principal products was: Gold, $52,515,548; silver, $42,690,226; lead, $24,551,632; copper, $71,712,527. The company employs 12,179 men (excluding Mexico), and paid in wages $10,212,591.

Attention is directed to the diversity of the company's interests and operations. It is now refining and marketing gold, silver, lead, copper, zinc, nickel, platinum, arsenic, bismuth, cadmium, tellurium, selenium and palladium. It is also engaged in the manufacture of sulphuric acid and coke.

In welfare work the company has been active. The 3-shift, or 8-hour system has been adopted wherever practicable, less than 6 per cent of the labor working more than 8 hours. Wages have remained practically the same under the 8-hour system as when longer hours prevailed. Conservation of health of operatives and provisions for their safety have received attention. Life insurance has been taken out by the company in favor of the wife or family of the operatives, in the sum of $500 for unmarried men and $1000 for married employes. The pension fund now amounts to $520,238. During 1914 pensions were granted to 63 applicants, the average age of whom was 62 years.

The United States Smelting, Refining & Mining Co. shows in its ninth annual report, covering the calendar year 1914 earnings of all companies, $2,932,519; depreciation, $666,877; profit, $2,265,642; dividends, $2,228,891; undistributed surplus, including surplus from previous year, $4,515,591.

Metals produced in 1914: Copper, 17,946,659 lb.; lead, 64,443,260 lb.; silver, 9,936,237 oz.; gold, 124,719 oz. The percentage in value of each metal was: Copper, 18.9 per cent; lead, 18.9; silver, 42.1; gold, 20.1.

The company has experienced the usual difficulties incident to the wars in Mexico and Europe. In April the company's American staff was obliged to leave Pachuca, Mexico. The Mexican staff remained on the ground and continued operations on a small scale. Expenses have been met, but no profit was made. No property damage has been done and the employes have not been molested.

The exploration department had presented for its consideration 639 properties. Of these 538 were rejected on an office examination of reports and data. A preliminary examination was made of 82, and 19 were accorded a complete examination. No purchases are reported. The company has been investigating the possibilities of oil fields in California, Wyoming and Mexico.

The American Zinc, Lead & Smelting Co. reports a total profit in 1914 amounting to $186,157, from which a net profit was carried to surplus account of $65,692. While conditions in the zinc industry were not satisfactory, nevertheless they were better than in 1913, when the company incurred an operating loss of $91,656. The European war, however, has made the United States the center of the spelter industry, and as long as the war lasts the price of spelter will be at a high figure. The company's smelters have a capacity of 110,000 tons of concentrates per annum and should produce 50,000 tons of spelter, about 11 per cent of the total output of the United States.

The mill at the Tennessee property has been increased in capacity from 1000 tons a day to about 1600 tons. Sufficient ore is in sight to supply 1800 tons a day for more than ten years. Only a single mill was operated in Missouri. The Wisconsin properties are producing at a much greater rate than ever before. The Hillsboro smelter has been in successful operation. The Dearing smelter was closed in 1914, and the Dearing plant operates at only 20 per cent capacity. An arrangement has been made, however, to treat a part of the Butte & Superior concentrates, and both the Dearing and Caney plants are ready to operate at 75 per cent capacity.

The Tennessee Copper Co. in its annual report for 1914 gives ore production as 468,668 tons, and estimated ore reserves as 4,010,661 tons. Material smelted during the year, in tons, was as follows: Tennessee copper ore, 437,340; converter slag, 17,909; blast furnace slag, 21,664; sinter, 42,909; limestone, 20,258; matte, 83,182; total, 724,822; coke, 38,726. Copper production was 12,871,113 pounds, at an operating cost of $0.1184 per pound. The average price received for copper delivered during 1914 was $0.13706 per lb. The production of 60° Beaume acid was 210,163 tons, an increase over that of 1913, due chiefly to improved smelting conditions. Net sales of all products amounted to $3,307,365; gross earnings, $981,900; net earnings, $805,455; dividends, $600,000; reserve for depreciation, $100,000; surplus for the year, $50,767; total surplus, $1,908,207.

The Nipissing Mines Company's report for 1914 states that the year was one of the most profitable in the history of the company. Silver production amounted to 4,689,333 oz.; gross value, $2,516,064. Net receipts were $1,587,621. Production cost was 19.8 cents per ounce of silver, being 4.29 cents per ounce less than in 1913. Average price at which silver was sold, 55.36 cents per ounce; in 1913 it was 60.26 cents, the decline being due largely to the war. Ore reserves amount to more than 10,000,000 oz. silver, an increase of more than 500,000 oz. over 1913. Surplus amounts to $1,602,776, an increase of $343,715. Dividends amounted to 20 per cent or $1,200,000. There was no change in treatment at the high-grade mill, which handled 929 tons of Nipissing ore of average value of 2439 oz. silver and 965 tons of custom ore of average grade of 2421 oz. silver per ton. The market for cobalt-nickel residue was good for the first half year, but was cut off by the war. The net income from 1060 tons of residue was $42,344. The low-grade mill treated 79,009 tons of ore of average grade of 30.82 oz. silver per ton. The actual recovery by clean-up was 89.64 per cent. Research work on the grinding operations showed that while practically all the rock in the final tube-mill discharge was finer than 200-mesh. metallic silver was flattened and would not pass. Two Callow screens have therefore been placed in the tube-mill circuits and are recovering from 20 per cent to 25 per cent of the silver in the ore. The dirty metallics are cleaned on a Wilfley table. Notwithstanding the increased cost of cyanide and other supplies, the total cost of treatment in the low-grade mill was $0.14 per ton less than in 1913, amounting to $3.989, distributed as follows:

	Cost per ton
Crushing at mine	$0.125
Aerial tramway	.065
Surface tramway	.069
Picking plant	.204
Crushing and conveying	.048
Battery	.275
Tube mills and classifiers	.575
Desulphurizing and slime collecting	.304
Intermediate filtering	.111
Cyanide treatment	1.076
Cyanide filter	.138
Clarifying and precipitation	.288
Refining	.111
Heating	.118
Water supply	.036
Construction	.334
Residue dam	.059
Consulting	.050
	$3.989

The Iron and Steel Market

Buying of steel products suffered an abrupt reduction at the beginning of April by reason of the termination of a number of contracts written at lower prices than obtained in the corresponding contracts for the second quarter. In other lines the bookings have been undiminished. As the mills were fairly well provided with specifications operations have been continued through April at an average rate of about 70 per cent of capacity.

In bars, plates and shapes the placing of strictly new orders was somewhat discouraged by the advance of the mills to a basis of 1.20c. This was in accordance with a program announced by various large mills early in February, that their price would be 1.10c. for specifications to be filed during February, 1.15c. for March and 1.20c. for second quarter. Serious doubts were entertained whether the 1.20c. quotation would really become effective. The price was fairly well maintained in April, but the market was subjected to no serious tests by large inquiries.

The first half of April developing no new encouraging influences, sentiment in some quarters began to become less hopeful, but later in the month encouraging developments began to appear again. On April 20 the Lake Superior ore market opened, and the early sales were larger than had been expected. War orders were reported in greater numbers. The Pennsylvania railroad system announced a budget of $32,000,000 for the year, to cover new rolling stock, rails and track work in general, and while it was explained that this represented merely the limit of the possible expenditures the news was regarded as favorable and hopes were entertained that other railroads would be moved to enter the market also. The Youngstown Sheet & Tube Company, an important independent steel interest, made a large purchase of pig iron, although it was operating all of its four furnaces, this being the first large purchase of steel-making pig iron in the Pittsburgh district for months.

In the past few weeks the steel market has had two courses open to it. With no definite increase in consuming demand, and mills operating at only 70 per cent of capacity, it would be difficult if not impossible for the advances recently made in certain prices to be maintained, buyers would endeavor to restrict their purchases, and operations would probably eventually decline, though not to the exceptionally low rate of last November and December.

On the other hand, with a slight further increase in actual consumption mill operations would increase beyond 70 per cent, approaching rapidly the point at which deliveries of some products would fall behind, an occurrence that is always the signal for forward buying and for replenishment of stocks by jobbers and manufacturing consumers. The process is a familiar one in

the steel market, a fresh demand arising almost over night when the condition changes from one of buyers being able to obtain almost instant delivery against any specifications filed to one in which the buyer must wait a few weeks for complete delivery against a miscellaneous specification. Once the steel industry reaches such a condition, it is certain to operate at practically its fullest capacity for months. The gap to be bridged was not between 70 per cent and 100 per cent, but between 70 per cent and 80, 85 or 90 per cent, for after so long a period of restricted operations and with alien emigration in excess for a twelvemonth past it has been the general opinion that the steel industry could not open short notice operations at 100 per cent of its physical capacity.

The developments of the latter part of April have disclosed a decided balance of probability that the pendulum will swing in the direction of larger demand, resulting in forward buying, advancing prices and even, possibly, an actual "runway market."

Iron Ore

Since the Lake Superior iron ore interests abandoned their price agreement several years ago each season has been "opened" by one interest or another effecting sales, others immediately adopting the price level thus indicated. This year the first sales appear to have been made by W. P. Snyder & Company and selling at once became general. As had been expected for months, prices were the same as ruled in 1914 and 1912, 1913 prices having been 60c. to 65c. higher, as follows: Old range Bessemer, $3.75; old range non-Bessemer, $3; Mesabi Bessemer, $3.50; Mesabi non-Bessemer, $2.85 per ton 2240 lb. on Lake Erie docks, for 55 per cent ore in the case of Bessemer and 5150 per cent ore in the case of non-Bessemer. The prices are as low as have obtained at any time since 1904, and are really very low considering the royalties ruling and the cost of stripping large quantities of over-burden in the case of many operations. The net price of an ore is determined on a unit basis, 60 cents, an arbitrary freight adjustment, being added to the base price on dock, the total being divided by the number of units in the base ore. Thus the unit price on Mesabi non-Bessemer is approximately 6.7c. Between 50 and 53 per cent there is a straight adjustment, the unit price being increased above 53 per cent, while between 49 and 50 per cent the unit price is multiplied by one and one-half and between 48 and 49 per cent it is multiplied by two. Thus for 48 per cent ore—we are referring entirely to Mesabi non-Bessemer—the total deduction is five units or about 33c., making the net price on dock $2.52. The ore pays 60c. rail freight up to upper lake dock, 40c. vessel freight and 10c. dock charges, so that $1.42 would be realized at mine, a price which obviously affords profit only to mines operated under favorable conditions. Higher grade ores take care of themselves.

The opinion is expressed in ore circles that this season's movement down the lakes will be not less than 40,000,000 tons, against 32,000,000 tons in 1914 and 49,000,000 tons in 1913, the banner year.

Pig Iron

The spectacular movement in Buffalo pig iron, referred to a month ago, involved a total of more than 300,000 tons of iron, but on account of the low price at which the iron was sold, somewhat under $12 at furnace, the influence upon other pig-iron markets was depressing rather than stimulating and the pig-iron markets as a whole were decidedly quiet in April. There was, however, a fair movement in southern iron at $9.25, Birmingham, for prompt and at $9.50 for second half, while there was some fair buying of basic in the east, chiefly at cut prices. It may be found that the purchases of the Youngstown Sheet & Tube Company, made ten days before the end of the month, will prove of considerable sentimental importance. This interest operates four furnaces, but buys merchant iron when operating its steel departments at above 75 or 80 per cent of capacity. It purchased from W. P. Snyder & Company ,Ohio Iron & Steel Company and Andrews & Hitchcock Iron Company about 40,000 tons of basic, 17,500 tons of forge and 5000 tons of foundry iron for delivery to October 1 at practically current prices. This is the first large buying in the Pittsburgh district since December and the first buying by a steel works having furnaces of its own for many months. The market is quotable as follows: No. 2 foundry: delivered Philadelphia, $14 to $14.25; f.o.b. furnace, Buffalo, $12.50 to $13; delivered Cleveland, $13.25; f.o.b. furnace, Chicago, $13; f.o.b. Birmingham, $9.25 to $9.50; at valley furnaces, 95c. higher delivered Pittsburgh: Bessemer, $13.60; basic, $12.50; No. 2 foundry, $12.75 to $13; gray forge, $12.50 to $12.75; malleable, $12.75.

Steel

Actual market transactions in billets and sheet bars have been light, consumers being well covered by contracts of various form. Specifications against these contracts have been steadily increasing. Prices are largely nominal at about $19 to $19.50 for billets and $19.50 to $20 for sheet bars, f.o.b. maker's mill, Youngstown, and about 50c. higher f.o.b. maker's mill, Pittsburgh. Rods are $25, Pittsburgh.

Finished Steel

Finished steel prices are fairly steady but in most lines the market has not been under much pressure on account of the existence of old contracts. Plates are being shaded, particularly in the Chicago district. Galvanized sheet quotations are largely nominal, some mills withdrawing entirely from the market, on account of the acute scarcity of spelter. Wire products have not developed a real market at the nominally advanced price and are quotable at the first of the two advances made early in the year.

Current quotations are as follows for ordinary deliveries and are f.o.b. Pittsburgh unless otherwise noted:

Rails, standard sections, 1.25c. for Bessemer, 1.34c. for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.20c.

Shapes, 1.20c.

Steel bars and bands, 1.20c., base; hoops, 1.25c. to 1.30c.

Iron bars, 1.15c., Pittsburgh; 1.15c., Philadelphia; 1.15c., Chicago.

Sheets, blue annealed, 10-gage, 1.35c.; black, 28-gage, 1.80c. to 1.85c.; galvanized, 28-gage, 3.40c. to 3.50c.; painted corrugated, 28-gage, 2c.; galvanized corrugated, 28-gage, 3.45c. to 3.55c.

Tin plate, $3.20 to $3.35 for 100-lb. cokes.

Steel pipe, 80 per cent off list.

Steel boiler tubes (less than carloads) 3½-in. to 4½-in., 75 per cent off list.

Tennessee Copper Company's production of sulphuric acid has increased from about 600 tons a day to an average of over 700 tons, the maximum daily production having been 820 tons. Based on 350 operating days in the year, the annual production is at the rate of 245,000 tons of acid. It is reported that the profits derived from this phase of the business are sufficient to pay the entire dividends on $5,000,000 of outstanding stock.

The American Electrochemical Society in Its External Relations

BY F. AUSTIN LIDBURY

Presidential Address Before the American Electrochemical Society.

Eight years ago, when the American Electrochemical Society was last the subject of a presidential address,[1] the society was faced by many serious problems relating to its growth and the continuance of its existence. Finance, the provision of papers, the attendance at meetings, questions regarding publications, matters involving even its independence were the subject of anxious thought and discussion. The successful growth, both extensive and intensive, of the society since that time must be a matter of extreme gratification to those whose devotion, energy, and wisdom at an anxious period of its existence guided the society in the direction which has led to its subsequent well-balanced development.

There comes a stage in the development of every organization such as ours at which the cultivation of the primary objects of its existence no longer demands all its efforts; it becomes free to devote itself to external activities, and to represent its membership and what it stands for in the larger affairs of life. Of course, it need not do so. A voter need not exercise his franchise; but we do not call him a good citizen for the omission. An innocuous reputation for respectability and learning can easily be maintained by any scientific body which carefully avoids contact with objectionable external realities; but it is the kind of reputation which attaches to that paragon of respectability who "passed by on the other side." In the last few years this society has shown gratifying indications that it takes no such narrow view of its duties or its interests, and I hope and expect that its activities in external matters will be progressively intensified and broadened.

Perhaps as good an illustration as any of the direction in which our duties and our interests lie can be found by considering our relations to current tendencies in government. The extension of legislative and bureaucratic activities which the last few years have seen has been too widely regarded by intelligent persons as a manifestation which would play itself out, on the principle that "if the fool would persist in his folly, he would become wise." Not only has this optimistic expectation not borne fruit, but reliance on it has to a large extent prevented the offer of information and guidance from those in a position to give it. There are signs that men of business are realizing their mistake in the matter, and it is time that the man of science and the engineer also realized theirs. What cannot be averted can at least be guided into intelligent channels.

The engineer—take the word in its widest sense—has been worrying about these matters for a long time, and occasionally he comes to the conclusion that what is needed is representation of himself in legislative bodies.[2] He had better remember that legislation is really lawyers' business. If the scientific and engineering professions would worry less about their "status" and pay more attention to making their opinions heard and their recommendations respected, they would cease to be bothered about the undue proportion of lawyers in legislative bodies.

For, on the whole, these lawyer-legislators are not so scornful of information and advice as we are inclined to believe. They try to get both whenever they can, and, when the practical business man, the technical man, the engineer held aloof, they went to the university professor and, when he was not available, to the charlatan and the agitator. They have shown their power of discrimination by preferring the professor; they instinctively felt that he knew more. If his guidance has led them into difficulties, it is because his truths are too often colored by his theoretical idiosyncrasies and not founded on a pragmatic basis. Until we have given the legislator all the assistance in our power, we are obviously not in any position to accuse him of spurning it. Nor does it particularly matter if he does, for the power of an intelligent minority, however small, is tremendous, and there is no man more sensitive to well-informed criticism of sufficient publicity than your legislator unless it be your bureaucrat.

I have attempted to indicate the extent to which the intelligence of government of a democracy is dependent upon the coöperation of its intelligent elements, and the extent of the responsibility in this regard of those professions which claim to embody the application of intelligence to industrial operations. A little self-examination will show that a well-defined portion of this responsibility rests upon the American Electrochemical Society.

We need have no false modesty about it, either in regard to what we represent or to what we are. We represent a branch of the chemical industry whose products are of such importance to the general industries of the country that, in spite of its youth, its absence at the present time from among the industries of the country would cause such industrial disturbance that the plaint of the wearer of many colors, always imminent but not up to the present moment audible, would pass unnoticed.

As a society, we are unusually representative. We embrace in the personality of our members and in the scope of our discussions the practical as well as the theoretical, the commercial as well as the technical; as a consequence our organization is capable of considering all phases of any question which comes within its scope. We have had a healthy growth, and our functions are normal; we do not suffer from overgrowth or uncorrelated parts, nor are we weakened by the overdevelopment of any particular activity. We have a representative constitution and its consequence, a responsible and responsive management. Finally, we are entirely independent, not only of outside influences, but also of any one class of internal opinion; the diverse nature of our membership guarantees us against the dangers of a narrow point of view.

Our duties are proportional to our possibilities. It will not be necessary for us to look around for subjects to which to devote our attention; many of these are clear; on some we have already made a beginning, some, still more important, we have not had the temerity to touch.

Perhaps there is no subject which will better illustrate our sins of omission (in common, I hasten to add, with many technical bodies equally interested in the matter) than our inaction in regard to legislation concerning water power. This is not the occasion on which to discuss the limitations which have been imposed upon the development of power at Niagara Falls; nor if it were, should I be able to add anything to the treatment of the subject by my predecessor in his presidential address at the last New York meeting.[3] I wish not to touch upon the controversial aspects of that question, but to point out that we have allowed the whole matter to go by default.

A combination of fortunate circumstances enabled our industry to grow in the last twenty years to the point where we are somewhat more than independent of foreign manufactures in electrochemical lines. What we do not suffer from we do not realize, and while almost

everyone who reads the newspapers is able to growl at the comparatively small development of the organic chemical industry in this country, an appreciation of what the same condition in the electrochemical industries would mean is probably not general, even among our own members.

It was not alone the reliability of Niagara power or its comparative cheapness which made it a vital factor in the development of our industries; it was the combination of these with a favorable commercial location. It is quite possible that had the development of power at Niagara Falls been prohibited from the beginning instead of throttled in its infancy the growth of electrochemical industries in this country might so have fallen behind that in other lands as to make us as dependent in this respect as, for instance, we are for dyes. We owe it to ourselves, both individually and as a society, to take every opportunity of bringing about a widespread knowledge of this situation. The electrochemical industry is already paying the penalty in the way of increasing scarcity of power and rising prices in the Niagara district, for allowing matters to take their own course.

Turning to the broader aspects of power development, we find that curious ideas have received governmental sanction, and even action, without any attempt at correction by us. For instance, that water-powers could be best developed by preventing people from developing them—we actually approved of this idea in a solemn resolution[4]; that conservation and the interests of the people and particularly efficiency would be best subserved by preferably connecting water-power plants to the loads of precisely the lowest load factors known.[5] If ideas of this description are acted on through lack of careful and intelligent controversion, who is to blame for the result—the ignorant, or those who know and keep silent?

I turn to patent legislation. Here we have, chiefly through the tireless energy of one of our past presidents, a record of some activity. But much more ought to be done. The combined efforts of many societies such as ours have succeeded in averting some very serious consequences of ignorance, but the whole question calls for a great deal of constructive effort. I know of no matter which presents to us so many difficult aspects, and not the least difficult is the danger that in trying to do justice to the "inventor" we may fall into the error (so common among inventors themselves) of regarding him as "the whole thing" So many of us have to take a matter where the inventor leaves off and make it work that we know better; we have a peculiar knowledge of this subject, and it is our duty to see that it is not overlooked.

We are governed more and more by commissions, officers and bureaus. Insofar as the operations of these agencies are of a restrictive nature, untoward results, where they occur, are usually due to ignorance being left to its own resources. A watchful readiness to extend co-operation, advice, information and assistance in matters which come within our scope will help to correct this.

It is likely, however, that we shall come more frequently in contact with agencies of a constructive nature, of which the scientific bureaus of the government may be taken as typical. These do a great work, and our respect and admiration for it is likely to be proportional to our knowledge of it. Their primary purpose coincides with our own, the assistance of the application of knowledge to industry. To a great extent their usefulness will depend upon us and our *confrères* in related lines, upon the use we make of them, upon the fertility of the suggestions they receive, upon the extent of the support of their efforts. It is so easy to take beneficial activities for granted that it is necessary continually to remind ourselves that a given amount of energy devoted to the support of existing valuable agencies will produce many times the results which would follow its application in other directions. The cultivation of many fields of investigation which would otherwise lie dormant because, being everybody's business, they are nobody's business, constitutes a peculiarly useful branch of governmental activity and we ought by suggestion and support to lend every possible assistance to those to whom it is entrusted.

The development of such relations with them would result in a duty of another description falling upon us as representing the people in these matters; in so far as such governmental activities touch upon our sphere, we should impose a measure of accountability. We should assist in checking expenditures on unnecessary work, or on duplication; we should insist, in view of the conception of bureaucratic infallibility held by the uninformed, on accuracy of statement in governmental publications, and of the elimination from them of collections of untrustworthy or incorrect information. We should carefully examine the recent tendency to regulate certain branches of industry nearly related to ours by instruction, by suggestion, even by the development of industrial processes.

Some aspects of this tendency are open to serious objections on principle; but it is evidently with us for trial at least, and we must do what is possible to encourage its useful, to discourage its harmful aspects. We should insist upon a careful checking of all statements of the commercial aspects of governmental work of this description as well as of its technical features. It is impossible to believe that governmental agencies such as I have alluded to could fail to gain in value by the inculcation of a sense of responsibility to the technical societies of the country. It would probably reduce the temptation to play to the gallery; it would at any rate prevent the deplorable spectacle of a member of the cabinet announcing a technical discovery originating in his department in terms of combined ignorance and extravagance of claim which would almost justify exclusion from the mails if employed by an ordinary company promoter.

Multiplication of instances in quite other fields of action would be easy; I have taken quasi-political cases because they afford perhaps the best illustrations, but I must turn, however, to the consideration of means, of the "adjustment of internal to external relations." The stimulus must come largely from the individual, the unofficial member. He must be ready to bring up subjects of general interest; the officers and the board must be equally ready to afford facilities for their general discussion and their thorough consideration by active and competent committees. However intense and unanimous the feeling of the membership may be upon any particular matter, the effectiveness of its expression will necessarily depend in the last resort upon the energy and ability of some committee. There is an unusual abundance of suitable committee material in this society, and there will be no difficulty in getting matters in which you are sufficiently interested properly handled. The discussion of external matters at our meetings would also tend to stimulate the exercise of the power of individual members for educating the uninformed.

Coöperation with other societies should be not only willingly given, but sought after. In general, coöperation with other societies forms an extremely important part of our external activities. Even the little which has been done has been productive of results. A single

[5] Cf. Met & Chem. Eng., 11, 117 (1913).

joint meeting, for instance, with the Electroplaters' Association some years ago has not only led to a considerable increase in interest in electroplating work in our own society, but has given the impetus to some very interesting and promising developments in electroplating circles in more than one locality. But the most interesting steps in inter-society coöperation have been taken for us by our flourishing New York Section during the last few years. We are indebted to that Section and to its capable chairman for showing us to what extent many dominant subjects need joint sessions for their proper presentation and discussion; and that brings me to the suggestion that the encouragement of local sections is the readiest means of fostering a healthy internal and external development. By their very nature they are able to maintain a much more continuous chain of interest; they come more readily in contact with the problem of the moment, the external problem; they touch it with less hesitation, less formality.

I cannot conclude without expressing my admiration of the excellent example which the editor of "Metallurgical and Chemical Engineering" has set us in the editorial pages of his journal; pages which have often so thoroughly represented the society in external affairs that we may very well be pardoned, though not excused, for having felt any exertions on our part possibly superfluous.

Notes

The Caloris Company announces the removal of their factory from Philadelphia to Millville, N. J. There it is located along their own glass house so as to provide better facilities for handling orders for glass tubes, laboratory glass ware, etc.

The **Oneida Community, Ltd.**, makers of the well-known Community Silver Plate, have completed and equipped a new factory at Kenwood, N. Y., and have now transferred the last of their various departments from Niagara Falls, N. Y., to this new plant. This move was made necessary to avoid the deleterious effects on the silver plate of the fumes from various chemical companies in the vicinity. It is said that the Niagara Falls plant which they have vacated is especially suitable for electrochemical work and may be leased on very advantageous terms.

The **Buffalo Forge Company**, of Buffalo, N. Y., has recently issued three interesting new catalogs. No. 200 relates to the "Buffalo planoidal fans," a modification and improvement on the older type of steel plate heating and ventilating fans with a comparatively small number of radial blades. With the improvements in design embodied in it, this type of fan is expected, for many conditions, to compete on an equal basis with the multiblade fans. Catalog 201 relates to "Niagara conoidal fans." Besides having all the advantages of the multiblade type in respect to higher operating speeds, more compact arrangement, and greater rigidity, the shape of blades and proportion to the housing used in the Niagara Conoidal, make it possible to convert into static pressure the velocity head, which is much higher proportionately to the total pressure with multiblade fans than with types having few blades. Catalog 182-E is a summary for convenient reference of the various types of blowers and exhaust fans, which are regularly built for direct connection to motors. This includes everything from large ventilating and drying fans down to the little Baby Conoidals for ventilation of moving picture booths, drying cabinets, etc., and electric blowers for single forge fires, which take less than half the horsepower of an ordinary electric lamp.

Hardinge Amalgamator.—The Hardinge amalgamator is a new invention of Mr. H. W. Hardinge, president of the Hardinge Conical Mill Company. While a full technical description is being withheld until the patents have been issued, the amalgamator is being tried in several Western mills. The adjoining diagram shows balls of gold amalgam (containing 50 to 60 per cent gold) from the Hardinge amalgamator

BALLS OF GOLD AMALGAM FORMED IN HARDINGE AMALGAMATOR

attached to the 8-ft. x 22-in. Hardinge pebble mill in the Plymouth Gold Mining Company's plant at Plymouth, California. These amalgam balls are formed by rolling around in the amalgamator and picking up small particles of gold in conjunction with mercury.

The Money Value of Radiated Heat.—In the Chamber of Commerce Building, Detroit, Mich., a retail store room is located directly over the boiler room and the heat from the latter was quite objectionable. In order to decrease the radiation of heat from the boilers and steam lines the engineer of the building insulated the settings and steam drums with Nonpareil Insulating Brick and recovered some of the steam lines and pump cylinders with Nonpareil High Pressure Covering. The cost of the Insulating Brick and Steam Covering was $214.84 and the application was made by the regular crew at odd times. Not only was the temperature above the boilers reduced 30 deg. by the use of this insulation, making conditions far more comfortable in the store above, but it was found that heat losses were reduced to such an extent that one boiler would carry the load which formerly required two. As the load in this plant varies but slightly it was an easy matter to obtain the fuel savings by comparing the records of coal consumption before and after the insulation was installed. In 1913, before the insulation was applied, the coal consumption in the six months from April to September was 224,960, 229,950, 218,790, 238,120, 224,630, 211,490 lb. respectively or a total of 1,347,940 lb. For the corresponding period in 1914, after the insulation was installed, the consumption was 183,190, 181,930, 180,690, 179,470, 176,000, 174,290 lb. or a total of 1,075,570 lb. This shows a net saving of 272,370 lb. of coal—136.185—tons costing $2.95 per ton. This is equal to $401.75 or over $800 per year—nearly four times the cost of the insulating materials, which were responsible for this saving.

The Spanish Government has prohibited the exportation of potash.

New Orleans Meeting of the American Chemical Society

Symposium on the Contributions of Chemistry to the Industries of the United States

The fiftieth meeting of the American Chemical Society was held in New Orleans, La., from Wednesday, March 31, to Saturday, April 3. Southern hospitality made the meeting a notable and highly successful and delightful event in the history of the society. The chairman of the local committees in charge of the different functions at the meeting were Messrs. W. L. Howell, C. S. Williamson, Jr., B. P. Caldwell, J. L. Porter, P. Asher, G. B. Taylor, L. A. Becnel, S. J. Tremoulet, and Mrs. E. J. Northrup.

The hotel headquarters were at the Grunewald Hotel, where many of the sessions were held. But the opening session, with the symposium on contributions of chemistry to American industries, was held in Gibson Hall, Tulane University, on Thursday morning, April 1. The attendance at this session was about 250.

President Charles Holmes Herty called the meeting to order and speeches of welcome were made by Mayor Martin Behrman and President Robert Sharp of Tulane University. President Herty replied for the Society.

Then Dr. Arthur D. Little of Boston, Mass., started the symposium with a very able address on "the industrial resources and opportunities of the South." The presentation of papers on contributions of chemistry to nineteen different American industries followed. The lecture by Dr. Bernhard C. Hesse of New York in the evening may be considered as the conclusion of the symposium. This lecture was delivered at the Hotel Grunewald.

CHARLES HENRY HERTY, PRESIDENT
AMERICAN CHEMICAL SOCIETY

SOCIAL FUNCTIONS AND EXCURSION

On Wednesday a smoker on the steamboat Sidney on the Mississippi river was greatly enjoyed by 300 members and guests including ladies. The cabin of the boat was festooned with smilax and gray Spanish moss. It was a very pretty Southland scene. A darky band furnished the music. Dinner was served. There was an entertainment afterwards and, of course, dancing. The party returned to New Orleans at 10 p. m.

On Friday evening a banquet was held at the restaurant de la Louisiane. The attendance was 200. Messrs. Alciatore served a real Creole dinner. Professor B. T. Caldwell of Tulane University was toastmaster and addresses were made by President C. H. Herty, Dr. W. L. Howell, Dr. C. L. Alsberg and Dr. C. L. Parsons.

There were some very interesting excursions during the convention week.

On Wednesday afternoon a party of 30 went through Henderson's sugar refinery.

On Friday afternoon a visit was paid to the New Orleans water purification plant by the Water, Sewage & Sanitation Section. About 50 members were taken to the plant in automobiles.

On Saturday afternoon a party of 20 visited the sugar refinery at Chalmette, while another party devoted the whole of Saturday to an excursion to the Weeks Island salt mines. About 110 took part in the excursion. The hotel was left at 7.15 a. m. in special cars and a special train of the Southern Pacific was taken at Algiers depot. Drs. Baekeland, Herty, Hillebrand and Parsons were in the party. The island was reached at noon. It is a knoll or lump about 150 feet above gulf level. The party went down into the mine, 600 feet below the surface, 20 at a time. The area of the mine is at present 20 acres. No timber is used in the mine construction. The salt is blasted down—pure rock salt crystals of 99.99 per cent purity. There seems to be an almost unlimited supply. The Myles Salt Company operates the mine. The hospitality of the place was tendered personally by Mr. Beverly Myles. The party left the salt mine at 3 p. m. and reached New Orleans at 8 p. m. It was a delightful day.

SECTION MEETINGS

On Friday meetings of the different divisions were held all day long at the Grunewald Hotel and fairly well attended. 153 papers were presented.

There are now eight sections of the American Chemical Society as follows:

Agricultural and Food Chemistry, Secretary, G. F. Mason, H. J. Heinz Company, Pittsburgh, Pa. Chairman Floyd W. Robinson was in charge.

Biological Chemistry, Secretary, I. K. Phelps, Bureau of Chemistry, Washington, D. C. Chairman C. L. Alsberg was in charge.

Fertilizer Chemistry, Secretary, F. B. Carpenter, Virginia-Carolina Chemical Company, Richmond, Va. Chairman J. E. Breckenridge was in charge.

Industrial Chemists and Chemical Engineers, Secretary, S. H. Salisbury, Jr., Lehigh University, South Bethlehem, Pa. In absence of the chairman, G. P. Adamson, the proceedings of the section were in charge of H. E. Howe.

Organic Chemistry, Secretary, C. G. Derick, 619 Indiana Ave., Urbana, Ill., who presided in absence of the chairman.

Pharmaceutical Chemistry, Secretary, A. P. Sy, University of Buffalo, 24 High Street, Buffalo, N. Y. Chairman F. R. Eldred was in charge.

Physical and Inorganic Chemistry, Secretary, R. C. Wells, U. S. Geological Survey, Washington, D. C.

Water, Sewage and Sanitation, Secretary, Harry P. Corson, State Water Survey, Urbana, Ill. Chairman Edward Barton was in charge.

The Industrial Resources and Opportunities of the South

The symposium on Thursday was introduced by a fascinating address by Dr. **Arthur D. Little**, of Boston, Mass., on the industrial resources and opportunities of the South.

"Only those who have stood upon the seashore and there endeavored conscientiously to place the Atlantic Ocean inside a quart bottle by the aid of a teaspoon will appreciate the temerity and difficulties involved in an attempt to present within the compass of a brief address the industrial potentialities of the South. Probably no one but a relative stranger to the South would make the attempt at all.". . .

"The awful spectacle of a world in arms which we are forced to contemplate today must recall with peculiar vividness to many men and women North and South the horrors and desolation of another struggle which was concluded, happily as we all now believe, just fifty years ago. When we consider that the wealth of the whole United States in 1850 was estimated at a little more than $7,000,000,000 and that the cost of the war to the South has been conservatively figured at $4,000,000,000, we may gain some faint notion of the material burden under which the South slowly arose to work out her destiny."

ARTHUR D. LITTLE

RESOURCES OF THE SOUTH

After giving some statistical figures, Dr. Little pointed out that agriculture is still and always will be the greatest business of the South and the backbone of its prosperity, although even now the value of manufactured products exceeds by nearly $90,000,000 the revenue from its farms.

As all the world knows, the South affords a peculiarly favorable habitat to the cotton plant and the 36,000,000 acres under cotton produce annually from 14,000,000 to 16,000,000 bales of the fibre, or about 65 per cent of the world's crop. In this connection it may be said in passing that chemists by developing methods for utilizing values in the cotton seed have added from $12 to $14 per bale, or perhaps $200,000,000 yearly to the value of this single crop, so that the seed alone is now worth nearly as much as the entire crop of 1860. Cotton and seed together constitute about 30 per cent of the total value of Southern farm products, excluding live stock. The ultimate products of the cotton plant together constitute 30 per cent of the merchandise exports of the Whole United States. The value of staple, linters and seed in 1913 was $911,000,000. Corresponding values for 1914 were $704,000,000, so that the European war may fairly be said to have cost the South, on this one item, over $200,000,000.

Strangers to the South do not commonly think of this portion of our country as a manufacturing community. They may, therefore, well be surprised to learn that already the manufactures of the South greatly exceed in value the products of its farms and reach the stupendous total of more than $4,000,000,000. In the 29 years from 1880 to 1909 the capital invested in the South in manufactures increased 900 per cent and the value of manufactured products 407 per cent. The census survey of the entire country enumerates 262 different lines of manufacture. Of these 236 are already carried on in the South.

The annual value of Southern lumber is about $350,000,000, but the reported cut excludes so many primary wood products of larger importance that at least another hundred million dollars must be added to represent their value and $25,000,000 more for naval stores.

Excluding lignite, the coal areas of the Southern states amount to about 88,000 square miles, or over 50 times the coal area of Germany, seven times those of Great Britain and twice those of all Europe, including Russia. The South's present proved reserves of coal are estimated at 530 billion tons, or 25 per cent more than the more thorough exploitation of all European countries has disclosed—and these Southern reserves comprise 75 per cent of all the coking coal in the United States. West Virginia alone has a far greater coal area than Great Britain and Germany combined, and she has mined less than 1/6 of one per cent of the 150 billion tons beneath her surface. Nevertheless, her 1912 output of 67,000,000 tons was 50 per cent more than all bituminous coal mined in the United States in 1880. Alabama already stands next to Pennsylvania in coke production.

With coal, limestone, and iron ore closely adjacent within her borders, Alabama has already demonstrated her ability to manufacture pig iron more cheaply than any other locality on earth and "he who has the iron will get the gold." Her present output of 2,000,000 tons is merely an earnest of her potentialities. The immediately available Southern iron ores are estimated at 2,600,000,000 tons, with even greater reserves of ores of lower grade. Together these constitute not less than 50 per cent of the total iron resources of the country.

It is doubtful if any American product is better known throughout the East than those tins of kerosene which bear the label of the Standard Oil Co. In 1890 the South produced less than half a million barrels of petroleum. In 1912 its output was 84,000,000 barrels. Passing by the great deposits of Louisiana and Texas, it may be pointed out that the oil production of Oklahoma alone in 1911 was 54,000,000 barrels.

More than 60 per cent of the natural gas output of the country must be credited to the South. About 5,000,000 hp in water power is available in the South and only about one-fifth of this power has been developed, and of this amount nearly 800,000 hp is in the five states of Alabama, Georgia, North Carolina, South Carolina and Virginia. Georgia alone has available 500,000 hp.

The lavishness with which Nature has bestowed her gifts upon the South is nowhere more apparent than in the extraordinary variety and range of what may be termed the secondary mineral resources of this fortunate section of our country. An output of $5800 worth of diamonds per week of the best South African quality in Pike County, Arkansas, is interesting and promises to become spectacular, but it shrinks to insignificance before many other Southern mineral products. The whole country knows the annual shipment of 8,000,000 boxes of Florida oranges and grapefruit, but relatively few of us give thought to the three million tons of the infinitely more important phosphate rock which Florida produces. This is about four-fifths of the country's output, practically all of which now comes from the South.

Portland cement requires for its manufacture an assured supply of limestone and clay or shale adjacent to cheap fuel. Nowhere are these conditions met more fully or more generally than in the South. As a result, its development of the manufacture of Portland cement has become one of the industrial miracles of the world. In 1890 the production for the whole United States was less than 400,000 barrels. In 1911 the output of cement in the Southern states alone was nearly 11,000,000 barrels.

Then the South has clays, gypsum, bauxite, sulphur. The largest sulphuric acid plant in the world is at Ducktown, Tennessee, but the striking feature of the installation which holds this record is that the acid is made from smelter fume, which commonly in other plants goes only to create a nuisance. The copper production, which is the primary output of the plant, is over 18,000,000 lbs. per year. The largest copper refining plant in the world is at Patapsco, Maryland, with an annual production of 200,000,000 lbs.

In 1911, 42 per cent of the lead output of the country came from the South and 41 per cent of the zinc production. The value of Missouri zinc alone was $14,000,000. The largest pyrites producing plant in the whole country is in Louisa County, Virginia.

THE FAILURES OF THE SOUTH

What are the failures to be charged against the South? First of all, there is the stupendous failure of its agriculture. In 1909 only about 18 per cent of the total area of the South was tilled, whereas 75 per cent is available for tilled crops. What is more to the point, the 110,000,000 acres which were tilled were tilled badly.

Next, perhaps, in importance is the failure of Southern lumbering, which is one of the most wasteful operations conducted on the whole broad face of the Earth. Upon a cut of 30,000,000,000 feet of yellow pine the South wastes not less than 15,000,000,000 feet, which intelligently utilized as raw material should yield ten times the profit derived from lumbering.

Then there is the enormous waste in natural gas. The waste of gas in the Oklahoma fields alone has been as high as 150,000,000,000 cubic feet a year, and is now annually not less than 25,000,000,000 cubic feet. Every 100,000,000 cubic feet of natural gas represents on the basis of a ten-hour day 588,000 horse power, if consumed in a fair gas engine on fluctuating load averaging 50 per cent of rated capacity.

The South contains over 50 per cent of the total iron resources of the country. Nevertheless, it produces only 12½ per cent of the pig iron made and consumes not over 150 lbs. per capita, while the figure for the whole country is 650 lbs. Here again we have before us the fundamental difficulty which confronts the South. A ton of iron ore shipped as ore returns only $2 and provides less than one day's work for one man. If shipped as stoves it returns $40 and has provided a day's work for ten men. The South has been selling raw materials. It should sell brain values and labor values.

Owing to its later advent as a large producer and its relatively more general introduction of by-product coke ovens, the South has been less wasteful than the North of the ammonia values in its coal.

An excellent example of intelligent conservation is afforded by the great pulp mill at Canton, North Carolina. Formerly the spent chips from the chestnut extract plants were burned. Now they are boiled in caustic soda and converted into high-grade pulp and paper.

One of the greatest of the relatively undeveloped potential industrial assets of the South is undoubtedly the negro. Scarcely any work carried on in the South today is more truly constructive or fraught with greater ultimate possibilities than that which goes forward at Tuskegee and in those other institutions of which it is the type.

THE GOAL OF THE SOUTH'S DEVELOPMENT

The first of the South's problems would seem to be the organization of rural life to make it richer, more satisfying, more profitable and pleasanter. It is bound up with the problem of the reorganization of Southern agriculture. *The South has really not begun to farm.*

Foremost among the industrial problems of the South would seem to be the suppression of wastes, the vastly greater development of labor values in its products and the keeping at home of money now needlessly spent elsewhere. The South has been too generally content with shipping crude materials and primary products and too ready to accept from other sections the things which it might better produce at home.

For gigantic wastes which may immediately be utilized to the enormous profit of the South no industry is comparable to the lumbering of yellow pine.

While Northern paper mills are paying on the average $18.37 for the wood to make a ton of paper, the South is throwing away tens of thousands of cords of pulp wood every day, only a cord and a half of which is needed to make a ton of Kraft paper, worth $70. The ultimate development of a vast paper industry in the South is assured. But men are needed—captains of industry.

"Several types of gas producer are now operating profitably on wood waste. New methods of controlled distillation have been developed and applied to wood, and it has been proved both by the Forest Service and our own laboratory that turpentine and rosin may be profitably extracted from stumps and lightwood by processes which permit the manufacture of paper from the extracted chips. The production of lumber in the South will ultimately become a mere incident in the business of lumbering. No longer then will logging tramways be pulled up the moment the saw logs on the tract have been removed. They will stay until the tract is cleared of cord wood, pulp wood, lightwood, stumps, and saw logs. The cleared land will be devoted to grazing or to farming under the stimulus of demonstration farms or corporation management and the lumber mill become the center of a whole group of highly profitable industrial activities.

"Less than 30 per cent of the lumber produced in any Southern state receives any further industrial handling in the state of origin. Cotton seed oil is shipped to Chicago and to Berlin, New Hampshire, to be hydrogenated and converted into lard and butter substitutes. Bauxite is sold for $5 a ton to be subjected elsewhere to the purifying treatment, which raises its value to $60. The South will one day benefit enormously by a cheap process of producing alumina direct from clay. It will give new values to Southern clay beds and to Southern water powers and transfer the aluminum industry to this section. It does not appear, however, that any effort is being made in the Southern states to develop such a process.". . .

"No locality in the United States, and perhaps none in the world, presents such advantages for the establishment of the great basic chemical industries as Louisiana. Here in close juxtaposition are found cheap salt, even cheaper sulphur, gas, oil, rosin, turpentine and wood waste, while nearby are the coal and minerals of Arkansas and Alabama.

"It is noteworthy, in view of the extraordinary opportunities for chemical development presented by the South, that in the Southern states are to be found only about 10 per cent of the chemists of the country as represented by the membership of the American Chemical Society.". . .

"Fragmentary and utterly inadequate as this attempted presentation of Southern resources has proved to be, it will have served its purpose if it has brought freshly home to some of you who live in this supremely favored section of our country the responsibility for individual initiative imposed upon you. Opportunity implies responsibility. Gentlemen, you are heirs to an imperial inheritance and its responsibilities are yours."

Contributions of the Chemist to Various American Industries.

After Dr. Little's very able address the symposium of papers on the contributions of the chemist to nineteen different American industries was begun. These nineteen papers were presented mostly by others than their authors. Dr. Baekeland read Mr. Ash's paper. The meeting adjourned at 12.30, when Dr. Horne's paper had been reached. Dr. H. A. Houston's illustrated lecture on the potash industry of Stassfurt occupied the afternoon session and the other papers of the symposium were presented on the next day in the convention hall at the Grunewald Hotel. Advance copies of the symposium papers were available. We herewith give a concise resumé of all of them.

Contributions of the chemist to the **California wine industry** were covered in a paper by **Charles S. Ash.** The chemist began to be of value to the wine industry only when he became familiar with the wine business and became a wine man. One of the chief problems he has solved is to assure the stability of the wine. Preservatives were first used, such as salicylic acid and benzoic acid, but the pure food laws have stopped this, and all attempts looking for a preservative that cannot be detected, have been in vain. But what the chemist has done in solving the problem of the production of a stable wine is the establishment of the fact that by proper methods of handling the use of preservatives becomes unnecessary. Further, by chemical control of the "blending" operation, he has insured the uniformity of the product as completely as seasonable difference will allow. Moreover, by chemical control, he has reduced the spoiled wine from 25 per cent to less than 1 per cent (about 0.46 per cent average). Finally he has reduced the quantity of inferior wine from 25 per cent to 5 per cent. (Some grapes always give inferior wine no matter what care is given to the products). In spite of earlier temporary discouragements, the wine chemist is now having more intimate relations to the wine industry.

The contributions of the chemist to the **copper industry** were the subject of a paper by **J. B. Francis Herreshoff,** vice-president of the Nichols Copper Company and consulting engineer of the General Chemical Company. The output of copper in the United States was 17,500 long tons in 1874; 64,708 in 1884; 158,120 in 1894; 362,739 in 1904; and 563,700 in 1912. It was not until after 1890 that the real value of chemists in improving operations in mining, as well as in concentrating, roasting, smelting, and refining copper was fully appreciated. Chemical analyses permit chemical control of concentration as well as of roasting and smelting. The United States mines produce more than 50 per cent of the copper of the world; 75 per cent of the copper of the world is refined in this country and the larger proportion of this refining is done by electrolysis. In carrying on this electrolytic work, the chemist has been responsible for a very large proportion of the improvements that have been made in the last 20 years. Copper wire for electrical purposes must be of highest purity such as can only be obtained by electrolysis; for instance, a quarter of one per cent of arsenic in copper cuts down its electrical conductivity from 101 to 45.

Contributions of the chemist to the **corn products industry** were discussed in a paper by **E. T. Bedford,** president of the Corn Products Refining Company. The industry of glucose and grape sugar, or, as it is known in this country, the industry of corn products, is based upon an epoch-making discovery of a chemist—the conversion by chemical means of starch into reducing sugars. Owing to the character of the raw material employed in this country—corn—the products are no longer limited to two; the chemist has added to them until their number now exceeds one hundred. The corn manufactured into corn products in this country amounts to 50,000,000 bu. per year. It is converted into 800,000,000 lb. of corn syrup, 600,000,000 lb. of starch, 230,000,000 lb. of corn sugar, 625,000,000 lb. of gluten feed, 75,000,000 lb. of oil and 90,000,000 lb. of oil cake.

The chemist soon recognized the large possibilities which lay in the utilization of certain constituents of the raw material which were allowed to run to waste. First among these were the nitrogenous substances, commonly classified under the name of "gluten." Their running to waste was dropped; the product was collected, washed and dried, and put upon the market as a cattle feed. The recovery of the outer hull of the corn, the bran, and the development of the corn oil industry followed.

Contributions of the chemist to the **asphalt industry** were the subject of a paper by **James Lewis Rake,** secretary of the Barber Asphalt Paving Company. Chemistry, in the service of the asphalt industry, has converted it from one which originated on purely empirical lines into one which is now founded on a rational and highly scientific basis. The chemist has given his assistance in the preparation of fluxes or heavy oils of suitable character, and in the fixing of a standard for the grading of the sand and the nature and amount of filler or powdered stone which enter into an asphalt pavement. Aside from this, he has studied the nature of the native bitumens which are the components of asphalt and has differentiated the various types which are found in nature. In fixing the characteristics of the asphalts and the various petroleums from which fluxes and residual pitches are obtained, he has made it possible to describe these materials with such accuracy in specifications that they are readily differentiated.

The contributions of the chemist to the **cottonseed-oil industry** are covered in a paper by **David Wesson,** manager of the Technical Department of the Southern Cotton Oil Company. The industry was started in the fifties of the last century by one or two mills in New Orleans. In 1872 as much as 52,705 tons of seed were crushed. This amounted to 4 per cent of the entire crop of 1,317,637 tons. In 1913, with a production of 6,305,000 tons 4,767,800 tons were crushed, or 75.6 per cent of the entire crop. The estimated average cost per ton was $25.35, and the total value of the seed alone was $120,850,000, while the value of the products was $156,600,000. About 1890 "chemistry began to take the industry in hand. Crude oil, up to now, had been bought and sold as prime, or prime for the season, or off, and was passed upon by manufacturers and brokers, who looked at it, tasted it, then looked wise and gave their verdict. Then the chemist stepped in and found that the quality of the oil closely followed the free-acid present, and started grading accordingly. This made a big stir. Some of the mill owners denied the possibility of free fatty acid being present in any of their oil, as they never had any fatty acids on their premises. The chemists then showed these same mill men how much oil they were losing in their cake and throwing away in their hulls, with the result that more oil was made per ton of seed.

"The hulls were burned under the boilers and furnished the power for the mills. Every ton of seed furnished about 700 lb. of hulls. The ashes, averaging about 10 lb. per ton of seed were a valuable by-product, being rich in potash and phosphoric acid.

The writer is in doubt whether it was a chemist or a cow that discovered that hulls were good for cattle food. At any rate, cows ate them with avidity, and analyses proved that they had the feeding value of low-grade hay. So the mills now get from $4 to $10 a ton for hulls which were worth about $1 to $2 per ton as fuel.

"The cotton-seed soap stock in the early days was almost thrown away. Much was made into woolen and scouring soaps. About 1877, a bright near-chemist mixed some of this soap with soda ash, and made it into washing powder. The advertising man made a virtue of its yellow color, and the 'twins did the work.' Now, the soap stock is used as a source for white distilled fatty acids and glycerine, while the residual tar from the stills forms a base for paint and roofing materials."

But the chemist's greatest service to the industry has been in the refining of the oil. His achievements are summed up as follows: He has put the refining of crude oil on a more rational basis and prevented loss in manufacture by making a physical audit by analytical methods of the work of mills and refineries. By analyses of products their values have been shown, and the commercial practice has been placed on an accurate foundation. By improving refining methods, practically all cottonseed oil, regardless of section, or season, has been converted into one of our most valuable food products, and the residue worked into valuable by-products. By the new process of hydrogenation wholesome edible fats of the consistency of butter and lard are now produced entirely from what will probably continue to be our cheapest vegetable oil. While the chemist has worked to improve the manufacturing side of the industry, he has been the means of putting something like $125,000,000 every year in the hands of the farmers; or, in other words, he has added ten to twelve dollars to the value of the crop for every bale of cotton grown and has made possible an industry which provides means of livelihood for the thousands of people in hundreds of factories and on the road making and selling the products.

Contributions of the chemist to the **cement industry** were the subject of a paper by **G. S. Brown,** president of the Alpha Portland Cement Industry. "The tremendous advance made in this industry has been, for the most part, due to the zeal and knowledge of the chemist." Portland cement has been manufactured in Europe for very many years and in the latter part of the nineteenth century was imported into the United States in large quantities. Then by chemical research it was established that with the materials available in this country it was possible to manufacture cement really of a better quality than that hitherto imported. A broader field was opened by reduction of the cost in manufacture, due to the use of powdered coal as fuel, the increase in the size of the kilns, and the handling of the raw material in large quantities direct from the quarry. Further work has been done by the chemist in the working out of standard specifications, in the development of a water-proof cement, etc. "The fact that the chemist is responsible for the quality of the cement to such an extent that he controls the operation of the mill, is largely advertised by at least one of the larger cement manufacturing companies in the United States."

Contributions of the chemist to the **sugar industry** were discussed in a paper by **W. D. Horne,** who reviewed the past, present and future. In the manufacture of raw sugar, the past quarter century has seen great advance through bringing factories under chemical control, and the cane industry has caught up with and surpassed the beet industry through its scientific development on these lines. The consumption of sugar in the United States has risen from 1,500,000 tons in 1890 to 3,750,000 tons in 1914 and the per capita consumption from 54 lb. to 84 lb. per year. This has been partly due to the cheapening of sugar through scientific management in its production, raw sugar having fallen from 2.88 cents per lb. (without duty) in 1890, to 2.03 per lb. in 1914, and this, too, in spite of a rise in price of all other food staples, averaging considerably over 15 per cent.

In making raw sugar the proper defecation and clarification of the juice are chemical matters of first importance and during twenty-five years great improvements have been made in the double carbonation process both for beet and cane, the use of sulfitation of the thin carbonated juice, and the use of phosphoric acid and its salts as additional defecating materials. Kieselguhr has been introduced by Wiechmann as a clarifying agent and is now being used more and more extensively, especially since the development of the great Lompok deposit in California. Raw sugar factories are now producing white sugar directly from cane as well as from beet, due to chemical investigations of the matter and chemical control.

Raw sugar factories are now generally able to sell their molasses instead of throwing it away, because of chemically developed methods of converting it economically into alcohol, cattle foods when mixed properly with bagasse, peat moss, etc., and into other useful products. The sugar is all recovered from beet molasses by the Steffens process of conversion into tricalcium saccharate, and the by-products from this are going into fertilizers, cyanides, etc. Wax is recovered from scums and the residues utilized as fertilizers in the cane fields. Paper is made from the unused fiber of the cane and another by-product has been improved by the chemical investigations of the manufacture of rum.

In sugar refining, due to chemical research, invention and control, progress has been made all along the line. This and another work done in many laboratories is concisely sketched in the paper and the author concludes that the future contributions of chemistry to the sugar industry will probably be found in simplified processes of defecation, cheapened materials for color removal, etc., more energetic chemical treatment of low-grade products and a better utilization of such by-products as are inevitable.

The contributions of the chemist to the **incandescent gas-mantle industry** were discussed in a paper by **Sidney Mason**, president of the Welsbach Company. "No article more strikingly emphasizes the importance of the science of chemistry than does the incandescent gas mantle, which owes both its inception and development, up to the towering output in the United States alone of upwards of 80,000,000 mantles annually, to the untiring effort of chemical research." The paper was naturally a concise summary of the work of Auer von Welsbach and his coworkers.

Contributions of the chemist to the **textile industry** were discussed by **Franklin W. Hobbs,** president of the Arlington Mills, and past president of the American Cotton Manufacturing Association. He sketched the contributions of chemistry to bleaching, dyeing, the production of dyestuffs, mercerization of cotton, and manufacture of artificial silk. "The annual production of artificial silk is now fully 20,000,000 lb. There are various processes—collodion, gelatine and viscose. The viscose process now seems to command the field and is developing rapidly in quantity and

quality produced. Here is a case where common wood pulp worth a few cents a pound, by a touch of the chemist's art, is changed to a beautiful silk-appearing yarn worth from $2 to $3 a pound."

Contributions of the chemist to the **fertilizer industry** were discussed in a paper by **H. Walker Wallace**, manager of the general sales department of the Virginia-Carolina Chemical Company. The chemist discovered the necessity of the industry by studying the composition of soils and plants. He first suggested the production of superphosphate and established its manufacture. The process of manufacture has been gradually improved so that the insoluble phosphoric acid has been reduced from two to three per cent to a fraction of one per cent. He was responsible for the manufacture of sulfuric acid, which is necessary for the production of superphosphate. He has produced a double superphosphate containing from 45 to 50 per cent available phosphoric acid. His researches have made it possible to convert many waste products into valuable plant food constituents, which are utilized in fertilizers. The nitrogen of the air has been combined and converted into forms suitable for plant nutrition. The chemist has worked out processes for saving the nitrogen in flue gases and coke ovens and converting it into sulfate of ammonia. He has worked out formulas and blended the various fertilizer constituents into the compounds best suited for different soils and crops.

Contributions of the chemist to the **soda industry** were discussed in a paper by **F. R. Hazard**, president of The Solvay Process Company. The role of the chemist in industrial operations is to answer the question "why?" The chemist is the enemy of rule-of-thumb methods. He is not content to accept the superstitions and prejudices which have been handed down in all industry, but seeks to ascertain the causes underlying the effects which, in some cases at least, are produced with a considerable degree of regularity by the rule-of-thumb methods. It is only within the past twenty-five or thirty years that the chemist has been admitted as an important member of the manufacturing staff in our modern industrial life. Formerly the managers and owners of the business knew very little about the practical operation. They relied upon the secret formulas of the foreman. It is easy to see that the advent of the chemist was attended with great difficulties. He was regarded as their natural enemy by superintendents, and was looked upon with distrust by workmen. His experiments were ridiculed and not infrequently were purposely interfered with, so that their results would be without value. Thus early in his introduction into the industrial field, it became absolutely necessary for the chemist to tell the workmen, the superintendent, the manager, or owner, that none of them really knew their business, which unfortunately was the fact. . . . "The chemist must, therefore, exercise the patience of Job, he must have the wisdom of the serpent and the gentleness of the dove; he must be persevering and constantly alert to see the first signs which will lead him toward the answer to his question."

"As an illustration of the delicate position of the chemist toward the manufacturer, the following is taken from our own experience: About twenty-five years ago a soap-maker complained that 58 per cent alkali purchased from us was not as good for his purpose as 48 per cent alkali imported from England. After considerable correspondence it developed that his method of ascertaining this peculiar fact was to take, say, 100 lb. of each quality of alkali, dissolve each by itself in about a barrel of water and then determine the specific gravity of the solution by means of a Twaddle hydrometer. The 48 per cent alkali gave a somewhat greater specific gravity and he thereupon concluded that it was a superior article. As he was one of our important customers and a somewhat difficult man to deal with, it became necessary to convince him by his own methods that his conclusions were not correct. We prepared samples of several different kinds of alkali, also of common salt and of sulfate of soda, and, using the same hydrometer, we determined the density of each, whereupon it was found that on his theory it was an absolute waste of money for him to purchase alkali of any kind, as ordinary commercial sulfate of soda showed a considerably greater specific gravity than any of the other solutions. When confronted with this actual test, made on the same scale and using the same instrument as he had been accustomed to employ, our customer acknowledged, and continued for many years thereafter to make his soap by the use of our 58 per cent alkali." . . .

"Only last year, to show that the knowledge which a chemist can contribute is still of value, a complaint was made by a glass-maker that the 58 per cent alkali furnished to one of his works was inferior to that furnished at another. Correspondence developed the fact that the workmen at one point were also employed in handling lime and that the ventilation of the plant was not very good, while the conditions at the other plant were much better. The chief complaint was that the men in the one plant suffered seriously from sores; in fact, some of them were quite disabled. A personal investigation by one of our representatives showed that the unfortunate men were employed first in handling lime and then in unloading alkali, which was in bulk. The weather being quite warm and the exertion by no means easy, these men were establishing upon their own persons miniature caustic soda plants, and the resulting soreness and tenderness of the skin, if neglected, as was too often the case, led to rather serious conditions which required a long time to heal. An elementary knowledge of chemistry would have been sufficient to ascertain the cause of the difficulty."

Contributions of the chemist to the **leather industry** were the subject of a paper by **William H. Teas**, president of the Marion Extract Company. The author sketched the work of the chemist in preparing and using the different vegetable and mineral tanning materials.

Contributions of the chemist to the **flour industry** were the subject of a paper by **John A. Wesener** and **Geo. L. Teller.** The authors concisely summarize the principles of flour making. Chemistry assists in selecting and buying the grain; it helps to show the quality of the flour produced. It has supplemented mechanical processes of the mill and accomplished what had long been desired but could not be attained, in the improvement of color and baking qualities of the flour. By the introduction of baking-powder products it has made possible many delicacies in the way of pastry and biscuit and has made possible the great self-raising flour industry. It has helped to explain the intricate process of the fermentation of bread dough, has pointed out the way to fit flour for it, and has unlocked for investigating problems of bread production, which have, as yet, opened only enough to permit a glimpse of a large space filled with interesting and useful possibilities.

Contributions of the chemist to the **brewing industry** were discussed in a paper by **Gaston D. Thevenot.** In brewing biological considerations are as important as chemical ones. The influence of the

chemist makes itself felt first in the selection and preparation of the raw materials from which the beer is made. An enormous amount of energy has been expended by the chemist on the explanation and scientific control of the mashing process and great strides have been made in this field. The progress made in the fermentation of the beer during the last decades has been of the first magnitude. As far as the finished product is concerned, its clarification and sterilization have been given great attention. The problems of the disposal of former waste materials (spent grains, carbonic acid gas, yeast) have also been solved by the chemist.

Contributions of the chemist to the **preserved foods industry** were discussed in a paper by **R. I. Bentley**, vice-president and general manager of the California Fruit Company Association. A little over a century ago Appert, a French chemist, was awarded a prize by his government for discovering a process for preserving foods without the use of preservatives. Appert's process of hermetical sealing is the same in principle as that in use today by food preservers the world over. But the industry has grown to enormous proportions. New York City expends $150,000,000 annually for preserved foods—as much as that city spends for milk, bread and eggs combined for the same period.

Chemistry has enabled the food preserver to get the best materials suited to his use. A very simple illustration is that of salt—used to a large extent in the preservation of vegetables. Formerly, the preserver considered it a matter of economy to use the cheapest grade of salt that could be purchased. The chemist has shown him that some salt on the market contains injurious materials and that its use affects both the quality and appearance of products. Chemistry having already determined what grade of salt is best suited to his use, on its delivery the chemist determines whether the preserver has received what was selected. In the item of solder also, chemistry has enabled the preserver to get those proportions of metals which are best suited to his use, and on delivery the chemist tells him whether he has received what he ordered.

The services of the bacteriologist, besides the chemist, are needed in the food preserving industry to determine the best methods of processing. Among the applications of chemistry that have given the food preserver an improvement in the quality of his products is the improvement in the color of some varieties of fruit, such as berries, by the enameling of the inside of the can; also the examination of the water supply of the food preserver and the elimination of the objectionable elements in the water or the securing of a new supply. The almost complete elimination of iron in the machinery which comes in contact with the canner's products is due to the chemist pointing out the fact that the source of darkening or discoloration of the products was caused by the affinity of iron for tannin.

Chemistry has enabled the preserver to arrive at more economical methods of manufacture, particularly in the saving of labor and eliminating or reducing waste. Many fruits and vegetables are made ready for canning by immersing them for a few seconds in a solution of caustic soda, after which the fruits or vegetables are subjected to the action of fresh water sprays. In this manner the peeling is removed at a great saving in waste and labor without affecting the flavor of the fruit and vegetables so treated. By this method riper, and consequently better-flavored fruit can be handled than by the hand method of peeling. This method is now used almost exclusively on some varieties and is far more cleanly and sanitary than the old.

The most notable application of chemistry in the matter of utilizing the by-products of a food preserver is that of the pineapple waste in the Hawaiian factories. The sugar value in the waste is recovered and a syrup furnished to the preserver, whereby the use of cane sugar is almost entirely eliminated.

Contributions of the chemist to the **potable water industry** was the subject of a paper by **Wm. P. Mason**, professor of the Rensselaer Polytechnic Institute. The author sketched the development of the ideas as to what is required from a chemical analysis of potable water, and pointed out why in a large municipal filter plant a chemist and bacteriologist is continually needed on duty to prevent "pin-point coagulation" or an overdose in the use of "bleach," etc. To arrive at a complete estimate on the value of a water the chemist's knowledge is needed besides that of the bacteriologist.

Contributions of the chemist to the **celluloid and nitrocellulose industry** were the subject of a paper by **R. C. Schüpphaus.** All the applications of nitrocellulose in the arts are based on the fact that the structure of its various forms may be broken down by the action of suitable solvents. The discoverer of nitrocellulose was already in possession of its colloid solution. The differences between soluble and insoluble varieties (in certain solvents) were quickly recognized, and representatives of four great groups of solvents were known at the very dawn of the nitrocellulose industries, viz.: 1. Alcohols: Methyl and ethyl alcohols. 2. Ester: Methyl and ethyl acetates. 3. Ketones: Acetone. 4. Mixed solvents: Ethyl alcohol and ethyl ether.

With these fundamental facts to start from there began a long line of chemical activity. Among the industries developed, the manufacture of pyroxylin plastic occupies the first place, and the other developments, such as the production of photographic films, artificial leather, pyroxylin varnishes, and even artificial silk made from collodion may be regarded as offshoots from this branch. The activity of the chemist in this industry is twofold, covering research and control of operations. This is sketched somewhat more in detail in the paper and it is pointed out that there is not a factory of pyroxylin compounds of any importance in existence today that has not its busy staff of analytical, managing and research chemists.

Contributions of the chemist to the **glass industry** were discussed in a paper by **A. A. Houghton**, vice-president Corning Glass Works. Chemical research on glass was first necessitated for glass for optical purposes. The glasses originally available for optical purposes were made up of only five oxides—silica, potash, soda, lime, and lead oxide. Doebereiner (1829) introduced barium and strontium, Harcourt (1834) experimented with twenty other elements, and Otto Schott, since 1880, did very extended work on special glasses in conjunction with Professor Abbe and the Zeiss Company. Schott first used boric acid in glass, which is of greatest importance for optical glass. He developed not only optical glass, but thermometer glass, borosilicate glass for lamp chimneys, a compound glass for boiler water-gauge tubes, the Uviol glass for transmitting ultraviolet light, etc.

"America's contribution to the development of the glass industry, chiefly in methods of working and handling the molten glass, are epoch-making in character; along more strictly chemical lines creditable work has been done, as instanced by the Tiffany or Aurene glass, the selenium red, and others. Aside

from optical glass, on which a beginning is being made, the glasses produced in this country probably are fully equal in quality and variety to those produced abroad; and in some respects America is forging ahead."

Contributions of the chemist to the **pulp and paper industry** were the subject of a paper by **F. L. Moore,** president of the American Paper and Pulp Association.

It is hardly too much to state that the development of modern paper making and the enormous extensions of the use of paper in recent times have been due for the most part to the introduction of the three chemical processes by which wood fiber has been made available as a general substitute for rags. The author sketched the development of the sulphite process (which has now reached in the United States a production of over 5000 tons a day), the soda process, and the sulphate process, and pointed out how the paper and pulp industry has been vitally influenced by the new processes yielding cheap alkali and cheap bleaching powder, and other chemical inventions.

This paper concluded the symposium.

The Contribution of the Chemist to the Industrial Development of the United States

Dr. **Bernhard C. Hesse,** in a lecture entitled "The Contribution of the Chemist to the Industrial Development of the United States—A Record of Achievement," summarized the results of the chemist's work, brought out in the nineteen papers of the Symposium. For twelve of the nineteen industries covered in the Symposium the number of wage-earners and the value of manufactured products and the value added by manufacture is given in Table I*a* for the year 1909. For eighteen additional industries which make use of chemists in the control of their operations the corresponding figures are given in Table I*b*.

BERNHARD C. HESSE

For these thirty-one industries, the 0.01 per cent of chemists of our population directly affect 16 per cent of our wage-earners, 24.6 per cent of our manufactured values and 20.2 per cent of our values added by manufacture. This is a measure of the influence of the chemist upon the industrial development of the United States as a nation.

Table II gives a summary of the export trade between the United States and Germany for twenty-nine industries. The industries in which the United States is importer from Germany are given on the left hand of the table, those in which the United States is exporter on the right hand.

It is interesting to note that we sell Germany more lard than Germany sells us of potash and aniline and other coal-tar dyes put together; that we sell Germany half again as much refined petroleum as it sells us aniline and other coal-tar dyes; that we sell Germany practically the same amount of pig and scrap lead as Germany sells us of alizarin and anthracene dyes; that we sell Germany almost as much paraffine as Germany sells us of indigo, and so on through the list.

As a rule the things that we sell to Germany are from a chemical point of view, less refined, i. e., involve

TABLE I*a*	Wage-earners	Product value	Value added by manufacture
Wine	1,911	$13,120,846	$6,495,313
Copper	15,628	378,805,974	45,274,336
Fertilizer	18,310	103,960,213	34,438,293
Textiles	44,046	83,556,432	48,295,131
Canned and preserved foods	59,968	157,101,201	55,278,142
Cotton-seed oil	17,071	147,867,894	28,034,419
Cement	26,775	63,205,455	33,861,664
Sugar	20,730	327,371,780	52,523,806
Brewing	54,579	374,730,096	278,134,460
Leather	62,202	327,874,187	79,595,254
Glass	68,911	92,095,203	59,975,704
Paper and wood pulp	75,978	267,656,964	102,214,623
Chemicals (strictly)	23,714	117,688,887	53,567,351
Totals	529,823	$2,455,035,132	$897,688,496
TABLE I*b*			
Iron and steel	278,505	$1,377,151,817	$399,013,072
Petroleum refining	13,929	236,997,659	37,724,257
Lead smelting and refining	7,424	167,405,650	15,442,628
Illuminating and heating gas	37,215	166,814,371	114,386,257
Confectionery	44,638	134,795,913	53,645,140
Paint and varnish	14,240	124,889,422	45,873,867
Soap	12,999	111,357,777	39,178,359
Carpets and rugs	33,307	71,188,152	31,625,148
Explosives	6,274	40,139,061	17,328,113
Zinc smelting and refining	6,655	34,205,894	8,975,893
Turpentine and rosin	39,511	25,295,017	20,384,174
Oil cloth and linoleum	5,201	23,339,022	7,788,921
Chocolate and cocoa	2,826	22,390,222	8,867,162
Baking powder and yeast	2,155	20,774,588	11,436,603
Dyestuffs and extracts	2,397	15,954,574	6,270,923
Blacking, cleansing and polishing preparations	2,417	14,679,120	7,716,728
Wood distillation other than turpentine	2,721	9,736,998	3,861,147
Oleomargarine	606	8,147,629	1,650,997
Totals	513,020	$2,605,262,886	$829,052,389
Total for 31 chemical industries	1,042,843	$5,060,298,015	$1,726,740,885
Total for all industries	6,615,046	$20,672,051,870	$8,529,260,992

TABLE II—U. S. CHEMICAL TRADE WITH GERMANY (1913)

U. S. imports from Germany	Value in U. S. money	U. S. exports to Germany
	$75,000,000	1 Copper
	26,700,000	2 Lard
1 Potash salts	18,819,000	
	12,690,000	3 Refined petroleum
2 Aniline and other coal-tar dyes	7,290,000	
	4,970,000	4 Phosphate rock
	4,880,000	5 Oleomargarine
	4,585,000	6 Turpentine rosin
	4,460,000	7 Mineral lubricants
	3,840,000	8 Spirits turpentine
3 Caoutchouc	2,582,000	
	2,220,000	9 Crude benzine
	2,171,000	10 Beef tallow (prime)
	1,744,000	11 Nickel and nickel coin
4 Straw, esparto and other fibers; paper stock	1,649,000	12 Cotton-seed oil
	1,550,000	
5 Alizarin and anthracene dyes	1,463,000	
	1,421,000	13 Pig lead and scrap
6 Indigo	1,319,000	
	1,231,000	14 Crude and hard paraffine
	1,162,000	15 Acetate of lime
7 Platinum and allied metals	1,120,000	
8 Hops	952,000	
9 Miscellaneous volatile oils	941,000	
	903,000	16 Tin and tin scrap
10 Tin and tin scrap	900,000	
11 Potassium and sodium cyanide	845,000	
12 Chrome, tungsten, etc.	784,000	
13 Superphosphates	766,000	
	724,000	17 Crude wood alcohol
14 Beet sugar, refined	716,000	
	695,000	18 Carbides
	673,000	19 Miscellaneous volatile oils
15 Alkaloids exoquinone	672,000	
16 Toilet and tooth powders	658,000	
	656,000	20 Heavy benzine and patent naphtha
17 Lime-nitrogen, etc.	635,000	
18 Potash carbonate	632,000	
	617,000	21 Lubricants of fats and oils
	579,000	22 Beef and mutton tallow
19 Ferro-Al, Cr, Mn and Ni	567,000	
20 Potassium magnesium sulfate	509,000	
21 Gold ores	506,000	
	506,000	23 Copper alloys
22 Beet sugar, raw	492,000	
23 Aniline oil and salt	476,000	
24 Bronze and metal colors	473,000	
25 Glue	471,000	
26 Aluminum plates and metal	454,000	
27 Quinine and its salts	436,000	
	422,000	24 Portland cement
28 Terpineol and allied synthetics	409,000	
29 Gelatin	403,000	

less hard chemical intellectual work than do our imports from Germany. But this is so in our whole export and import business, not merely in chemistry.

With the record of which he has accomplished the American chemist can hold up his head with pride and self-confidence. That he has not done more is by no means due to any unwillingness. It is due in the largest part to the apathetic attitude of those in charge of the management of many of our industrial enterprises requiring chemical knowledge in their exploitation. Many of them fail absolutely in a chemical understanding of their own products and are devoid of any sympathetic contact with chemistry and with chemical points of view and therefore are incapable of, and unable to appreciate the value of chemical work or to have a wholesome understanding of the snares, the pit-falls and the tedium of chemical research.

The plea for the wider introduction of chemists into positions of managerial responsibility is, however, not to be interpreted into a statement that any kind of a chemist can do any kind of a chemical job. "In selecting your chemist for a responsible position you must look out that you do not get a square peg for a round hole, just as you would when engaging a man for any other position, but the trouble seems to be with many of those who have engaged chemists that they have not appreciated that there are chemists and chemists; they seem to have some sort of an idea that there is a magic about what a chemist does. Now, there is no magic at all. It is all plain, hard work, that calls for a lot of intellectual effort, and above all, the application of common sense which as every one knows, is a very rare article."

The second part of the lecture dealt with the criticisms of the American chemist which have been made by the daily press since the beginning of the European war on account of the fact that there is no complete American dye-stuff industry.

Broadly considered, the criticisms of the press may be grouped as follows: (1). The present shortage of dyes and inaccessibility of German producers to the American market offers an unusual opportunity for the manufacture of coal-tar dyes in this country. (2). The chemical manufacturer of this country should make those coal-tar dyes.

As to the first question, Dr. Hesse point out that there is no real shortage.

As to the second question Dr. Hesse referred to Lord Moulton's reasoning that one dollar's worth of dyestuffs is necessary to the production of $100 worth of manufactured product. The dividends declared and paid by the German dyestuff factories in 1912 are in the neighborhood of 10 per cent on the annual turn-over. For the purpose of discussion, let us assume it is 25 per cent and let us assume that the man who makes this $100 worth of manufactured product makes 10 per cent or $10 profit on that. The textile maker, therefore, makes $10 where the dyestuff maker can make 25 cents, or more likely 10 cents, if he can manufacture as cheaply as can the German. The American dyestuff and chemical manufacturer is not and has never been attracted by that possible 25 cents profit. The textile maker is spending that dollar anyhow to sombody; the American dyestuff and chemical maker does not care to make the dollar's worth of commodity. It is of no consequence to him in his business; he is making a living some other way, but the textile maker says it is a matter of life and death to him to get those dyestuffs.

An obvious question at this point is that if the dyes are so vital to the textile makers and the American dye makers will not make them, why do not the textile makers invest their money in a dyestuff plant and charge up any losses that they may sustain thereby as insurance premium to insure the sale of their goods and the profit therefrom resulting, just as they make their own soap, if need be? There is no ethical nor professional reason against their so investing their money.

"Granting that the stability of our textile and allied industries demand that these materials be produced in this country, it also follows that the financial burden and risk connected with the manufacture of the dyes should fall upon them. To this responsibility I have yet to see from the dye users of this country any adequate or sufficient answer?

"If patriotism will not induce buyers of cotton goods or sellers of cotton goods to pay more for goods made in the United States than for those made elsewhere, then why should patriotism cause the chemical manufacturers of this country to go ahead deliberately with a project in which they are sure to lose money?"

Some newspapers have suggested that the situation could be remedied by altering the policy of our patent laws by introducing requirements for compulsory working.

Dr. Hesse showed that the British working clause has been ineffective.

"The transplantation of the coal-tar dye industry to the United States is not a question of patent protection; it is nothing but an economic question, a plain matter of dollars and cents; those products can be made in this country if persons will buy those products at a fair margin of profit over the cost of domestic production, and since we know in advance that the cost of production here will be above the cost of production elsewhere, plus any prevailing duty, why should we go to the costly venture of spending millions of dollars to prove the obvious?"

"As a matter of fact, the whole world's coal-tar dye consumption is about enough to make a decent-sized business for one country. Ordinarily, it is best to do the world's work where it can be done best and to transport the products from their place of manufacture to their place of consumption. If it be necessary, for other reasons, that these products should be made elsewhere under conditions economically less favorable, then those who want those products made at such economically unfavorable place should bear the burden, but that is precisely what the dye users do not want to do; they want someone else to foot the bill.

"To bring the matter up squarely before you let me recapitulate: The 10,000 chemists in the United States are engaged in pursuits which affect over 1,000,000 wage-earners, produce over $5,000,000,000 worth of manufactured products and add $1,725,000,000 of value by manufacture each year; the business in products of and for chemical industry between the United States and Germany alone in 1913 provided 5 per cent of our total foreign business and 13.8 per cent of our balance of trade for that year. Please bear in mind that I am not by any means attempting to claim all the credit for this for the chemist; all that I ask is that his claim to recognition for intelligent, active and effective collaboration in bringing about those stupendous results be not thrown aside as worthless and that he shall not be made the target of unjust criticism because in 1914 there was a shortage of about $600,000 or 7 per cent in coal-tar dyes and because cotton dropped from 15 cents to 6 cents."

New Pyrometer and Instrument Manufacturing Concern.—The Gibb Instrument Company has been formed by Mr. W. H. Gibb for the manufacture and sale of thermoelectric pyrometers, potentiometers and the pyrochronograph. The offices of the company are in the Highland Building, Pittsburgh, Pa. Mr. Gibb has been in the pyrometer business for a number of years and is well known to the trade.

The Reburning of Lime from Alkali Waste and Other Forms of Precipitated Carbonate of Lime

BY RICHARD K. MEADE

Lime is used in a large number of chemical industries, among which may be mentioned the manufacture of caustic soda, bleaching-powder, calcium carbide, sugar, wood-pulp (by the soda process), glass and in the purification of water. In a number of these industries the lime does not enter the product at all but is obtained as a waste of the process in the form of precipitated calcium carbonate and may be converted into caustic lime again by the application of heat. Mixed with this calcium carbonate, which has been precipitated from solution and consequently is in a very finely divided state, is a large quantity of water, the latter amounting to three to five times the weight of the solid material in most cases.

Among those industries in which the lime is precipitated in the form of a carbonate, may be mentioned the manufacture of caustic soda, sugar, wood-pulp and in the purification of water. The lime obtained by most plants of the latter character, however, is small and it is only where water softening operations are extensive that sufficient carbonate would be obtained to justify an attempt to reclaim this. In the other three industries mentioned, however, the quantity of lime obtained is often very large and its recovery would represent quite an inducement provided it is done in a neconomical manner.
